Mechanics of the Function-Calling Process
When you invoke a function, the following actions occur:
1. JavaScript evaluates the arguments in the context of the caller.
2. JavaScript copies each argument value into the corresponding parameter variable, which is allocated in a newly assigned region of memory called a stack frame. This assignment follows the order in which the arguments appear: the first argument is copied into the first parameter variable, and so on. If there are too many arguments, the extras are ignored. If there are too few, the extra parameters are initialized to undefined.
3. JavaScript then evaluates the statements in the function body, using the new stack frame to look up the values of local variables.
4. When JavaScript encounters a return statement, it computes the return value and substitutes that value in place of the call.
5. JavaScript then removes the stack frame for the called function and returns to the caller, continuing from where it left off.

The Combinations Function
• To illustrate function calls, the text uses a function \( C(n, k) \) that computes the combinations function, which is the number of ways one can select \( k \) elements from a set of \( n \) objects.
• Suppose, for example, that you have a set of five coins: a penny, a nickel, a dime, a quarter, and a dollar:

  How many ways are there to select two coins?

  Penny + nickel
  Penny + dime
  Penny + quarter
  Penny + dollar
  Nickel + dime
  Nickel + quarter
  Nickel + dollar
  Dime + quarter
  Dime + dollar
  Quarter + dollar
  for a total of 10 ways.

Combinations and Factorials
• Fortunately, mathematics provides an easier way to compute the combinations function than by counting all the ways. The value of the combinations function is given by the formula

\[
C(n, k) = \frac{n!}{k! \times (n-k)!}
\]

• Given that you already have a fact function, it is easy to turn this formula directly into a function, as follows:

```javascript
function combinations(n, k) {
    return fact(n) / (fact(k) * fact(n - k));
}
```

• The next slide simulates the operation of combinations and fact in the context of a simple run function.

Exercise: Generating Prime Factorizations
• A more computationally intense problem is to generate the prime factorization of a positive integer \( n \).
• An integer is prime if it’s greater than 1 and has no positive integer divisors other than 1 and itself.
  ✓ 5 is prime: it’s divisible only by 1 and 5.
  ✓ 6 is not prime: it’s divisible by 1, 2, 3, and itself.
• Some prime factorizations:
PrimeFactorizations.js

Some thought questions and exercises:

• My solution relies on a single Boolean called first. What problem is first solving for us?

• During our trace of constructFactorization(180), factor assumed the values of 2, 3, 4, and 5. 2, 3, and 5 are prime numbers and therefore qualified to appear in a factorization? How does the implementation guarantee 4 will never make an appearance in the returned factorization?

• What is returned by constructFactorization(1)? How could you have changed the implementation to return "1 = 1" as a special case return value?

• Trace through the execution of constructFactorization(363) as we did for constructFactorization(180).

• Our implementation relies on a parameter named n to accept a value from the caller, and then proceeds to destroy n by repeatedly dividing it down to 1. Does this destruction of n confuse PrimeFactorizations’s for loop? Note that its counting variable is also named n.
