Lecture 14: API Servers, Threads, Processes

- An application programming interface (or API) is a set of library functions one can use in order to build a larger piece of software.
  - You're familiar with some APIs: `#include` files, system calls, and ad hoc protocols for driving and communicating with child processes using pipes and signals.
  - Very often these libraries reside on other machines, and we interface with them over the Internet.
- I want to implement an API server that's architecturally in line with the way Google, Twitter, Facebook, and LinkedIn architect their own API services.
- This example is inspired by a website called Lexical Word Finder.
  - Our implementation assumes we have a standard Unix executable called `scrabble-word-finder`. The source code for this executable—completely unaware it'll be used in a larger networked application—can be found right here.
  - Here are two abbreviated sample runs:

```bash
poohbear@myth61:$ ./scrabble-word-finder lexical
// many lines omitted for brevity
lexical
li
lice
lie
lilac
xi
poohbear@myth61:$
```

```bash
poohbear@myth61:$ ./scrabble-word-finder network
// many lines omitted for brevity
work
worn
wort
wot
wren
wrote
poohbear@myth61:$
```
I want to implement an API service using HTTP to replicate what `scrabble-wordfinder` is capable of.

- We'll expect the API call to come in the form of a URL, and we'll expect that URL to include the rack of letters.
- Assuming our API server is running on `myth54:13133`, we expect `http://myth54:13133/lexical` and `http://myth54:13133/network` to generate the following payloads:

```json
{
  "time": 0.223399,
  "cached": false,
  "possibilities": [
    "ace",
    // several words omitted
    "lexical",
    "li",
    "lice",
    "lie",
    "lilac",
    "xi"
  ]
}
```

```json
{
  "time": 0.223399,
  "cached": false,
  "possibilities": [
    "en",
    // several words omitted
    "work",
    "worn",
    "wort",
    "wot",
    "wren",
    "wrote"
  ]
}
```
One might think to cannibalize the code within `scrabble-word-finder.cc` to build the core of `scrabble-word-finder-server.cc`.

Reimplementing from scratch is wasteful, time-consuming, and unnecessary. `scrabble-word-finder` already outputs the primary content we need for our payload. We're packaging the payload as JSON instead of plain text, but we can still tap `scrabble-word-finder` to generate the collection of formable words.

Can we implement a server that leverages existing functionality? Of course we can!

We can just leverage our `subprocess_t` type and `subprocess` function from Assignment 3.

```c
struct subprocess_t {
    pid_t pid;
    int supplyfd;
    int ingestfd;
};

subprocess_t subprocess(char *argv[], bool supplyChildInput, bool ingestChildOutput);
```
Here is the core of the `main` function implementing our server:

```c
int main(int argc, char *argv[]) {
    unsigned short port = extractPort(argv[1]);
    int server = createServerSocket(port);
    cout << "Server listening on port " << port << "." << endl;
    ThreadPool pool(16);
    map<string, vector<string>> cache;
    mutex cacheLock;
    while (true) {
        struct sockaddr_in address;
        // used to surface IP address of client
        socklen_t size = sizeof(address); // also used to surface client IP address
        bzero(&address, size);
        int client = accept(server, (struct sockaddr *) &address, &size);
        char str[INET_ADDRSTRLEN];
        cout << "Received a connection request from "
                << inet_ntop(AF_INET, &address.sin_addr, str, INET_ADDRSTRLEN) << "." << endl;
        pool.schedule([client, &cache, &cacheLock] {
            publishScrabbleWords(client, cache, cacheLock);
        });
    }
    return 0; // server never gets here, but not all compilers can tell
}
```
Lecture 14: API Servers, Threads, Processes

- The second and third arguments to `accept` are used to surface the IP address of the client.
- Ignore the details around how I use `address`, `size`, and the `inet_ntop` function until next Wednesday, when we'll talk more about them. Right now, it's a neat-to-see!
- Each request is handled by a dedicated worker thread within a `ThreadPool` of size 16.
- The thread routine called `publishScrabbleWords` will rely on our `subprocess` function to marshal plain text output of scrabble-word-finder into JSON and publish that JSON as the payload of the HTTP response.
- The next several slides include the full implementation of `publishScrabbleWords` and some of its helper functions.
- Most of the complexity comes around the fact that I've elected to maintain a cache of previously processed letter racks and that I absolutely need to maintain a set of open `ingestfds` so overlapping calls to `subprocess`—that is, parallel calls to `subprocess`—work properly and without race conditions.
Here is `publishScrabbleWords`:

```cpp
static void publishScrabbleWords(int client, map<string, vector<string>>& cache,
                                   mutex& cacheLock) {
    sockbuf sb(client);
    iosockstream ss(&sb);
    string letters = getLetters(ss);
    sort(letters.begin(), letters.end());
    skipHeaders(ss);
    struct timeval start;
    gettimeofday(&start, NULL); // start the clock
    cacheLock.lock();
    auto found = cache.find(letters);
    cacheLock.unlock(); // release lock immediately, iterator won't be invalidated by competing find calls
    bool cached = found != cache.end();
    vector<string> formableWords;
    if (cached) {
        formableWords = found->second;
    } else {
        const char *command[] = {"./scrabble-word-finder", letters.c_str(), NULL};
        subprocess_t sp = subprocess(const_cast<char **>(command), false, true);
        pullFormableWords(formableWords, sp.ingestfd); // function exits
        waitpid(sp.pid, NULL, 0);
        lock_guard<mutex> lg(cacheLock);
        cache[letters] = formableWords;
    }
    struct timeval end, duration;
    gettimeofday(&end, NULL); // stop the clock, server-computation of formableWords is complete
    timersub(&end, &start, &duration);
    double time = duration.tv_sec + duration.tv_usec/1000000.0;
    ostringstream payload;
    constructPayload(formableWords, cached, time, payload);
    sendResponse(ss, payload.str());
}
```
Here's the `pullFormableWords` and `sendResponse` helper functions.

```cpp
static void pullFormableWords(vector<string>& formableWords) {
    stdio_filebuf<char> inbuf(ingestfd, ios::in);
    istream is(&inbuf);
    while (true) {
        string word;
        getline(is, word);
        if (is.fail()) break;
        formableWords.push_back(word);
    }
}

static void sendResponse(iosockstream& ss, const string& payload) {
    ss << "HTTP/1.1 200 OK\r\n";
    ss << "Content-Type: text/javascript; charset=UTF-8\r\n";
    ss << "Content-Length: " << payload.size() << "\r\n";
    ss << "\r\n";
    ss << payload << flush;
}
Finally, here are the `getLetters` and the `constructPayload` helper functions. I omit the implementation of `skipHeaders`—you saw it with `web-get`—and `constructJSONArray`, which you're welcome to view right here.

```cpp
static string getLetters(iosockstream& ss) {
    string method, path, protocol;
    ss >> method >> path >> protocol;
    string rest;
    getline(ss, rest);
    size_t pos = path.rfind("/");
    return pos == string::npos ? path : path.substr(pos + 1);
}

static void constructPayload(const vector<string>& formableWords, bool cached, double time, ostringstream& payload) {
    payload << "{" << endl;
    payload << " time: " << time << "," << endl;
    payload << " cached: " << boolalpha << cached << "," << endl;
    payload << " possibilities: " << constructJSONArray(formableWords, 2) << endl;
    payload << "}" << endl;
}
```

Our `scrabble-word-finder-server` provided a single API call that resembles the types of API calls afforded by Google, Twitter, or Facebook to access search, tweet, or friend-graph data.
