Direct numerical simulations of
turbulent non-premixed methane-air
flames modeled with reduced kinetics

By J. M. Card\textsuperscript{1}, J. H. Chen\textsuperscript{1}, M. Day\textsuperscript{2}, AND S. Mahalingam\textsuperscript{3}

Turbulent non-premixed stoichiometric methane-air flames modeled with reduced kinetics have been studied using the direct numerical simulation approach. The simulations include realistic chemical kinetics, and the molecular transport is modeled with constant Lewis numbers for individual species. The effect of turbulence on the internal flame structure and extinction characteristics of methane-air flames is evaluated. Consistent with earlier DNS with simple one-step chemistry, the flame is wrinkled and in some regions extinguished by the turbulence, while the turbulence is weakened in the vicinity of the flame due to a combination of dilatation and an increase in kinematic viscosity. Unlike previous results, reignition is observed in the present simulations. Lewis number effects are important in determining the local stoichiometry of the flame. The results presented in this work are preliminary but demonstrate the feasibility of incorporating reduced kinetics for the oxidation of methane with direct numerical simulations of homogeneous turbulence to evaluate the limitations of various levels of reduction in the kinetics and to address the formation of thermal and prompt $NO_x$.

1. Introduction

During the 1992 CTR summer program we studied the influence of finite-rate chemistry and transient effects on the structure of a turbulent non-premixed flame using DNS (Chen et al. 1992a, 1992b, Mahalingam et al. 1994). In this DNS, the combustion chemistry was approximated by an Arrhenius single- and two-step model. While these simple mechanisms provide useful insights for modeling under conditions ranging from near equilibrium to near extinction, they do not, however, relate the flame structure and extinction characteristics to the underlying elementary chemical-kinetic steps (typically more than 100 reactions) necessary to describe the combustion process in hydrocarbons. But the incorporation of such detailed chemistry for simulations at turbulent Reynolds numbers of practical interest is technologically infeasible at the present time. Thus, it is desirable to introduce reduced chemical-kinetic mechanisms for the description of the combustion chemistry (Smooke 1991). These mechanisms are deduced from a detailed mechanism by

\textsuperscript{1} Sandia National Laboratories
\textsuperscript{2} Stanford University
\textsuperscript{3} University of Colorado at Boulder
the systematic application of steady-state approximations for intermediate species. The combustion kinetics are then described by a few (two to five) global reactions, in which only the most elementary kinetic steps are retained and the concentrations of various intermediate species are represented by algebraic relations. Computations employing reduced mechanisms have successfully been accomplished for laminar, planar hydrocarbon, and hydrogen flames (Peters and Rogg 1993). Recent progress has also been made using reduced kinetics in simulations of reacting flows of $H_2 - O_2$ systems (Baum et al. 1992, and Montgomery et al. 1993).

The primary objective of this study is to evaluate the effect of different levels of reduction of fuel oxidation kinetics on methane-air turbulent diffusion flame structure and extinction characteristics.

2. Reduced chemistry for flame structure

The oxidation of methane can be described by the following reduced mechanism (Seshadri and Peters 1988):

$$\begin{align*}
\text{CH}_4 + 2\text{H} + \text{H}_2\text{O} & \rightleftharpoons \text{CO} + 4\text{H}_2, \\
\text{CO} + \text{H}_2\text{O} & \rightleftharpoons \text{CO}_2 + \text{H}_2, \\
2\text{H} + \text{M} & \rightleftharpoons \text{H}_2 + \text{M}, \\
\text{O}_2 + 3\text{H}_2 & \rightleftharpoons 2\text{H} + 2\text{H}_2\text{O}.
\end{align*}$$

These global reactions were deduced from a 40-some-step starting mechanism by the systematic application of steady-state assumptions for the intermediate species. The global rates for the above reaction can be expressed in terms of the elementary rates shown in Table 1, namely

$$\begin{align*}
\omega_{II} &= \omega_1 = k_{18}[\text{CH}_4][\text{H}], \\
\omega_{II} &= (k_{18}/K_3)[\text{H}][\text{CO}][\text{H}_2]/(K_2) = [\text{CO}_2]/(K_2/K_3), \\
\omega_{III} &= \omega_{III} = k_{17}[\text{H}][\text{O}_2][\text{M}], \\
\omega_{IV} &= k_{17}[\text{H}][\text{O}_2][\text{M}] = [\text{H}]^2[\text{H}_2\text{O}]^2/[\text{H}_2]^{5/2}K_1K_2K_3^2,
\end{align*}$$

where partial equilibria were assumed for elementary steps (2) and (3). In the above rates, the $K$'s are equilibrium constants, the $k$'s are the elementary rate constants, in which the numbering is selected to agree with Peters and Rogg (1993), and where $i$ is the concentration of species $i$. Moreover, the concentration of the third body is $[M] = 6.5[\text{CH}_4] + 6.5[\text{H}_2\text{O}] + 1.5[\text{CO}_2] + 0.75[\text{CO}] + 0.4[\text{O}_2] + 0.4[\text{N}_2] + 1.0[\text{other}].$

If we further assume that the H atom is in steady state, we get

$$\omega_{IV} = \omega_{II} + \omega_{III},$$

and the four-step mechanism reduces to the three-step approximation

$$\begin{align*}
\text{CH}_4 + \text{O}_2 & \rightleftharpoons \text{CO} + \text{H}_2 + \text{H}_2\text{O}.
\end{align*}$$
Turbulent non-pretized flames

\[
\begin{align*}
CO + H_2O & \rightleftharpoons CO_2 + H_2, \\
O_2 + 2H_2 & \rightarrow 2H_2O,
\end{align*}
\]

with rates for steps I, II, and III given by Eqs. (1-3), respectively.

Equations (1),(3), and (4) may be employed to show that

\[
[H] = (1 - k_{3f}[CH_4]/[k_{1f}(O_2)]) - k_{3f}[M]/k_{1f})^{1/2} \{O_2\}^{1/2} [H_2]^{3/2} (K_1 K_2)^{1/2} K_3/[H_2O].
\]

Assuming partial equilibrium for the water-gas shift (eq. II) results in a two-step mechanism, and a one-step mechanism may be obtained by assuming \(H_2\) (and hence, CO also) to be in steady state. The rate for the global step \(CH_4 + O_2 \rightarrow CO_2 + H_2O\) is taken from Bui-Pham (1992), namely, \(k = 5.2 \times 10^{12} \exp(-14906/T)\) (units are moles, cm, s, degK, and KJ/mole). For comparative purposes, future calculations will consider the rate constant determined by Puri (1987).

The four-, three-, and one-step kinetic mechanisms and the corresponding global rates are the basis for the present study.

3. Governing equations and numerical method

The governing equations are the continuity, momentum, species, and energy equations written in Cartesian tensor notation as follows:

\[
\frac{\partial \rho}{\partial t} + \frac{\partial \rho u_i}{\partial x_j} = 0, \tag{5}
\]

\[
\frac{\partial \rho u_i}{\partial t} + \frac{\partial \rho u_i u_j}{\partial x_j} = -\frac{\partial p}{\partial x_i} + \frac{\partial \tau_{ij}}{\partial x_j}, \tag{6}
\]

\[
\frac{\partial \rho Y_a}{\partial t} + \frac{\partial \rho Y_a u_j}{\partial x_j} = -\frac{\partial}{\partial x_j} (\rho Y_a Y_{aj}) + \omega_i, \tag{7}
\]

\[
\frac{\partial \rho e_i}{\partial t} + \frac{\partial (\rho e_i + p) u_j}{\partial x_j} = \frac{\partial (\rho u_i r_{ij})}{\partial x_j} - \frac{\partial q_j}{\partial x_j}, \tag{8}
\]

where

\[
\tau_{ij} = \mu \left( \frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} - \frac{2}{3} \delta_{ij} \frac{\partial u_k}{\partial x_k} \right), \tag{9}
\]

is the stress tensor,

\[
e = e + \frac{1}{2} \sum_{k=1}^{3} u_k^2, \quad e = \sum_{\alpha=1}^{N} Y_\alpha h_\alpha - \frac{p}{\rho} \tag{10}
\]

is the total energy per unit mass of the mixture, \(e\) is the internal energy per unit mass, \(h_\alpha\) is the enthalpy of species \(\alpha\) given by,

\[
h_\alpha = h_\alpha^0 + \int_{T_0}^{T} C_{p_\alpha}(T')dT', \quad \alpha = 1, \cdots, N \tag{11}
\]
where \( h_{0} \) and \( C_{pa} \) are the corresponding enthalpy of formation and specific heat at constant pressure respectively. The heat flux vector is given by

\[
q_{j} = -\lambda \frac{\partial T}{\partial x_{j}} + \rho \sum_{\alpha=1}^{N} h_{\alpha} Y_{\alpha} V_{\alpha j}
\]  

(12)

and the species diffusion velocity is

\[
V_{\alpha j} = -D_{0N} \frac{1}{Y_{\alpha}} \frac{\partial Y_{\alpha}}{\partial x_{j}} \quad \alpha = 1, \cdots, N - 1
\]

(13)

where \( D_{0N} \) is the binary diffusion coefficient between species \( \alpha \) and the \( N \)-th species taken to be nitrogen. To ensure that the net diffusion velocity is zero, the constraint \( \sum_{\alpha=1}^{N} Y_{\alpha} V_{\alpha j} = 0 \) is enforced to obtain \( V_{Nj} \). The equation of state is

\[
p = \rho RT
\]

(14)

where \( R \) is the mixture gas constant given by

\[
R = R^{0} / \bar{W}, \quad \bar{W} = \left[ \sum_{\alpha=1}^{N} \left( \frac{Y_{\alpha}}{W_{\alpha}} \right) \right]^{-1}
\]

(15)

where \( R^{0} \) is the universal gas constant, \( \bar{W} \) is the average molecular weight of the mixture, and \( W_{\alpha} \) is the species molecular weight. The mixture averaged thermal conductivity is modeled through the approximation suggested by Smooke and Giovangigli (1991),

\[
\lambda = \bar{C}_{p} A \left( \frac{T}{T_{0}} \right)^{r} \quad \bar{C}_{p}(T) = \sum_{\alpha=1}^{N} Y_{\alpha} C_{pa}(T)
\]

(16)

where \( A = 2.58 \times 10^{-4} \) g/cm-sec, \( r = 0.7 \), and \( \bar{C}_{p} \) is the specific heat of the gaseous mixture. The individual species specific heats are obtained as polynomial functions of temperature using the Chemkin thermodynamic database (Kee et al. 1987). The diffusion coefficients are obtained by prescription of Lewis numbers for individual species through

\[
D_{0N} = \frac{\lambda}{\bar{C}_{p} \rho L e_{\alpha}}.
\]

(17)

The Lewis number data is obtained from Smooke and Giovangigli (1991). For the one-step mechanism, the Lewis numbers for CH\(_{4}\), O\(_{2}\), CO\(_{2}\), and H\(_{2}O\) are 0.97, 1.11, 1.39, and 0.83, respectively, for the three-step mechanism, the additional Lewis numbers for H\(_{2}\) and CO (0.3 and 1.1, respectively) were employed, and for the four-step mechanism, the Lewis number for H is 0.18. The other symbols in these equations have the usual meaning.

For the three-step reduced mechanism, conservation equations for six reacting species is considered (CH\(_{4}\), O\(_{2}\), CO\(_{2}\), CO, H\(_{2}\), and H\(_{2}O\)) and the mass fraction of
$N_2$ is obtained through the relationship $\sum_{a=1}^{N} Y_a = 1$, where $N = 7$. Based on the discussion in the previous section, the reaction rates for the six species are computed through the following expressions:

$$\dot{\omega}_\text{CH}_4 = -W_{\text{CH}_4}\dot{\omega}_I, \quad \dot{\omega}_\text{O}_2 = -W_{\text{O}_2}[\dot{\omega}_I + \dot{\omega}_\text{III}], \quad \dot{\omega}_\text{CO}_2 = W_{\text{CO}_2}\dot{\omega}_\text{III},$$

$$\dot{\omega}_\text{CO} = W_{\text{CO}}[\dot{\omega}_I - \dot{\omega}_\text{III}], \quad \dot{\omega}_H = W_{H_2}[\dot{\omega}_I + \dot{\omega}_\text{III} - 2\dot{\omega}_\text{III}],$$

(18)

and,

$$\dot{\omega}_H = W_{H_2}[\dot{\omega}_I - \dot{\omega}_\text{III} + 2\dot{\omega}_\text{III}].$$

For the four-step mechanism, $N = 8$, and seven reacting species ($\text{CH}_4$, $\text{O}_2$, $\text{CO}_2$, $\text{CO}$, $\text{H}_2$, $\text{H}_2\text{O}$, and $\text{H}$) are considered. The reaction rate for these species is given by:

$$\dot{\omega}_\text{CH}_4 = -W_{\text{CH}_4}\dot{\omega}_I, \quad \dot{\omega}_\text{O}_2 = -W_{\text{O}_2}\dot{\omega}_\text{IV}, \quad \dot{\omega}_\text{CO}_2 = W_{\text{CO}_2}\dot{\omega}_\text{III},$$

$$\dot{\omega}_\text{CO} = W_{\text{CO}}[\dot{\omega}_I - \dot{\omega}_\text{III}], \quad \dot{\omega}_H = W_{H_2}[4\dot{\omega}_I + \dot{\omega}_\text{III} + \dot{\omega}_\text{III} - 3\dot{\omega}_\text{IV}],$$

(19)

and,

$$\dot{\omega}_H = W_{H_2}[2\dot{\omega}_\text{IV} - \dot{\omega}_\text{III} - \dot{\omega}_I], \quad \dot{\omega}_H = 2\dot{\omega}_\text{IV} - 2\dot{\omega}_I - 2\dot{\omega}_\text{III}. $$

The dimensionless form of the governing equations is obtained through definition of appropriate reference quantities based on the air stream properties. The sound speed at infinity $a_{\infty}$, corresponding density $\rho_{\infty}$, and the dynamic pressure $\rho_{\infty}a_{\infty}^2$ are used for the velocity, density, and pressure reference quantities. The reference temperature is $(\gamma_{\infty} - 1)T_{\infty}$ where $\gamma_{\infty}$ is the ratio of specific heats at temperature $T_{\infty}$ of the air stream. The reference fluid properties used are $\mu_{\infty}$, $\lambda_{\infty}$, and $C_{p\infty}$ corresponding to air at temperature $T_{\infty}$. A reference length scale $L_{\text{ref}}$ is chosen to be the distance between the fuel and oxidizer jets in the opposed diffusion flame used to initialize all the dependent variables in the computational domain. The equations are solved using a standard sixth-order accurate compact finite differencing scheme (Lele, 1992) for approximating spatial derivatives, and a third-order Runge-Kutta scheme for time advancement. A modified version of the Navier-Stokes Characteristic Boundary Condition (NSCBC) procedure originally developed by Poinset and Lele (1992), and suitably modified to account for variable specific heats is implemented. The boundary conditions are periodic in the $y$ direction and non-reflecting in the $x$ direction (see Chen et al., 1992a).

The turbulence field is prescribed by an initial two-dimensional turbulent kinetic energy spectrum function

$$E(k) = C_0 u_0^2 \left( \frac{k}{k_0} \right)^4 \exp \left[ -2 \left( \frac{k}{k_0} \right)^2 \right],$$

(20)

where $k$ is the wavenumber, $k_0$ is the wavenumber corresponding to the most energetic eddies, and $u_0$ is the rms velocity.
4. Initial conditions and flame parameters

The reacting flow field in a steady opposed jet diffusion flame configuration including a full 40 step chemical kinetic mechanism was obtained using the Sandia code OPPDIF. Pure methane and air at 1 atmosphere, 300 K with a strain rate of approximately 20 sec$^{-1}$ are the conditions imposed at the fuel and oxidizer jet separated by a distance of 1 cm. These correspond to low strain rate conditions. The strained laminar flame solution from OPPDIF was then allowed to relax to an unstrained condition in the DNS code. The unstrained laminar flame profile was used to initialize all of the species mass fractions, temperature, and density fields in the turbulence simulations.

The DNS was initialized in a two-dimensional computational domain with a plane laminar diffusion flame in the center of the domain. The fuel stream is on the left half of the domain while the oxidizer stream is on the right half of the domain. The velocity field was initialized with the turbulent kinetic energy spectrum given in (20). The turbulence Reynolds number was taken to be 57 based on the turbulence microscale. The flame is thicker than the turbulence microscale but smaller than the turbulence integral scale. Two-dimensional simulations were performed on a 120 by 120 grid.

5. Results and discussion

5.1 Laminar flamelet results

To initialize the direct simulations, the structure for laminar counterflow flamelets were calculated for low strain rates (< 100 sec$^{-1}$). The details for such calculations may be found in Smooke (1991). Shown in Figs. 1 and 2 are the flamelet structure in mixture fraction space for a global one-step reaction and a three-step mechanism, respectively.

A distinctive qualitative difference between the one-step and three-step mechanism is the breadth of the reaction zone. In Fig. 1c, it can be seen that the consumption of the fuel extends over a much wider range of mixture fraction for the one-step mechanism. The thinness of the fuel-consumption layer in multi-step mechanisms is one of the primary causes of resolution difficulties in direct simulations of turbulent combustion flames. In addition, it can readily be seen in Figs. 1b and 2b that the fuel and oxygen profiles are quite different. In the one-step approximation, fuel leaks through the reaction zone. However, for the three-step mechanism, only oxygen leaks through the reaction layer, which is in agreement with experiments and numerical calculations employing full detailed mechanisms.

Preliminary calculations using the four-step mechanism indicate that the qualitative features of the flamelet agree with previous studies. The major expected difference between the three- and four-step mechanisms is the H atom profile. In the three-step mechanism, all the H is produced on the fuel-lean side of the flamelet and is consumed entirely in the fuel-consumption layer. For the four-step approximation, the H atom profile is broader, in which the fuel-consumption layer is within the H nonequilibrium layer. The monograph by Smooke (1991) may be consulted for
more detailed discussion on the structure of laminar methane flames using reduced chemistries.

5.2 Turbulent flame structure

Preliminary results are presented here for the DNS using the global one-step mechanism described in section 2. Simulations are currently underway for the three- and four-step mechanisms. In order to resolve the fuel consumption layer the resolution
requirements are much greater for the three- and four-step mechanisms than for the one-step mechanism.

The turbulent two-dimensional DNS was postprocessed at 1.0 and 1.5 turbulent eddy turn times. This is sufficient time for the initial adjustment to occur between the imposed turbulence spectrum and the laminar flame. Instantaneous images of the vorticity magnitude, temperature, reaction rate, and species concentrations at $t = 1.0$ eddy turn time are shown in Fig. 3. It is evident from Fig. 3a that the
Figure 3. Computed fields at 1.0 eddy turn time for the one-step mechanism:
a) vorticity magnitude contours with stoichiometric mixture fraction, $f = 0.057$, b) temperature, c) $CH_4$ reaction rate with $f = 0.057$, d) $CH_4$ mass fraction, e) $O_2$ mass fraction, f) $CO_2$ mass fraction.
vorticity is greatly dampened in the vicinity of the reaction zone. The turbulence was initialized at all locations in the computational domain except near the outflow boundaries normal to the flame. Due to a combination of dilatational effects and a substantial increase in the kinematic viscosity with temperature, vorticity in the vicinity of the flame is dampened. Note in Fig. 3c that the vorticity is dampened more on the fuel side than on the oxidizer side. This is due to the lower density (higher temperature) that exists on the rich side of the flame which results in a higher kinematic viscosity on that side.

While the effect of the heat release is to weaken the turbulence, the effect of the turbulence is to wrinkle the flame. There are regions where the flame is locally extinguished as shown by the discontinuities in the reaction rate contour lines shown in Fig. 3c. At a later time in the simulation, $t = 1.5$ eddy turn times, the conditions are such that locally the strain rate is reduced in regions with hot products due to the heat release. The hot products act as an ignition source and in locations where fuel and oxidizer are present, the flame starts to burn once again. A comparison of Fig. 4 and Fig. 3c shows a region where reignition occurs. Previous simulations with simple chemistry (Chen 1992a, 1992b) did not report the occurrence of reignition.

It is also observed from the reaction rate contours and the stoichiometric mixture fraction line (Fig. 3c) that the flame does not always burn at the stoichiometric mixture fraction. Near the peak reaction rates the flame is stoichiometric; however, in regions that are curved toward the oxidizer stream the flame tends to burn lean, whereas in regions that are curved toward the fuel stream the flame tends to burn rich. We suspect that this is a Lewis number effect and that it is particularly pronounced in regions having the largest curvature. In regions that are curved toward
Figure 5. Scatter plots at 1.0 eddy turn time for one-step mechanism: a) temperature, b) CH\(_4\) reaction rate, c) CH\(_4\) and O\(_2\) mass fraction (o CH\(_4\). × O\(_2\)), d) CO\(_2\) mass fraction, and e) H\(_2\)O mass fraction.
the oxidizer, the defocusing of methane overcomes the greater mass diffusivity of methane \((Le = 0.97)\) over oxygen \((Le = 1.11)\). Hence, the flame tends to burn lean. On the other hand, in regions that are curved towards the fuel, the additive effect of focusing the methane combined with its larger mass diffusivity leads to a situation where there is an abundance of methane at the reaction zone. Hence, in this situation the flame tends to burn rich, and eventually, as the curvature becomes too large, the flame becomes too rich to burn, at which point local extinction occurs first at the flame tip. Since the reactant Lewis numbers in the DNS can readily be interchanged, these influences will be studied in greater detail in future simulations.

The reactant and product concentrations are presented in Figs. 3d-3f. Note that \(CH_4\) is more diffusive than \(O_2\). The products \(CO_2\) and \(H_2O\) follow the temperature (Fig. 3b) quite closely; hence, for the sake of brevity, only \(CO_2\) is presented in Fig. 3f.

Scatter plots of the temperature, \(CH_4\) reaction rate, and species concentrations in mixture fraction space are shown in Fig. 5. The mixture fraction, \(f\), is defined to be zero in the oxidizer stream and unity in the fuel stream. The maximum temperature occurs near the stoichiometric mixture fraction, \(f = 0.057\). The \(CH_4\) reaction rate peak is shifted slightly toward the fuel side. Consistent with the physical representation of the flame, the presence of both high and low values of the temperature and reaction rate in Figs. 5a and 5b suggests that there are regions in the flame that are fully burning as well as other regions that are being extinguished by the local strain-rate field. From Fig. 5c, note that there is leakage of both \(CH_4\) and \(O_2\) in this one-step model. Also, a significant portion of the flame is undergoing various stages of extinction as indicated by the spread of points between the equilibrium and frozen flow limits.

6. Concluding remarks

Preliminary results from DNS demonstrate that two-dimensional simulations of turbulent non-premixed methane-air flames modeled with reduced chemistry are feasible. The global one-step simulation required 50 cpu hours on a Cray-YMP. Extensions to three- and four-step mechanisms requires resolving the fuel consumption layer of the flame, a region that is approximately an order of magnitude smaller than the overall flame thickness. Simulations on a uniform grid will have enormous resolution requirements if the internal flame structure is to be fully resolved. This suggests a real need for a local adaptive mesh refinement capability for simulations of hydrocarbon flames.

Once the three- and four-step simulations are completed, detailed comparisons of the internal flame structure and extinction characteristics will be made. In particular, strain-rate and curvature statistics will be obtained and comparisons of the turbulence simulations with steady one-dimensional strained laminar flame predictions will be made. Finally, reduced mechanisms for the formation of thermal and prompt \(NO_x\) will be evaluated from the major species concentrations and the temperature.
