Figure S1. Correlations between height-related traits. (A) Subischial leg length vs. standing height $\left(R^{2}=0.829\right)$. (B) Sitting height vs. standing height $\left(R^{2}=0.620\right)$. The black, red, and blue dashed lines depict the regression lines for all individuals, hunter-gatherers only, and farmers only, respectively. Only individuals with measurements for both traits being compared were included in the comparison.

Figure S2. Bayesian estimates of population structure. STRUCTURE results for $K$ from 2 to 4 are shown. The figure follows the same format as Figure 3B.

Figure S3. Relationship between farmer admixture and body mass index. Scatterplots are shown of individual membership proportions in the blue "farmer"STRUCTURE cluster at $K=2$ (Figure 3B) and BMI. (A) 89 males $(r=0.166, P=0.060)$. (B) 69 females $(r=0.262, P=0.015)$. Only individuals with both standing height, body weight, and genetic data available were included. Symbols follow Figure 3A. The trend line is shown in black.

Figure S4. Effect of covariates on association signals. Quantile-quantile plots are shown comparing how the use of different covariates influence association signals for the 153,798 autosomal SNPs in the genetic dataset in EMMAX association analyses. (A) For the comparison of hunter-gatherer/farmer status, the effect of including no covariates (black; $\lambda=1.045$ ) is shown against the inclusion of ethnic category (green; $\lambda=1.026$ ) or the first two MDS dimensions (blue; $\lambda=1.003$ ) as a covariate. The effects of including hunter-gatherer/farmer status (red), ethnic category (green), or the first two MDS dimensions (blue) in addition to sex as a covariate versus only using sex as a covariate (black), shown separately for (B) standing height ( $\lambda=0.959, \lambda=0.900, \lambda=0.928$, and $\lambda=0.964$, respectively), (C) sitting height ( $\lambda=0.913, \lambda=0.888, \lambda=0.907$, and $\lambda=0.928$, respectively), (D) sitting/standing height ratio ( $\lambda=0.912, \lambda=0.883, \lambda=0.891$, and $\lambda=0.905$, respectively), and $(\mathbf{E})$ subischial leg length ( $\lambda=0.926, \lambda=0.896, \lambda=0.915$, and $\lambda=0.906$, respectively). The identity line appears in gray.

Figure S5. Association signals for adult standing height. EMMAX associations between adult standing height and 153,798 autosomal SNPs, considering the 159 individuals with standing-height measurements available (Table S1). (A) Manhattan plot. (B) Quantile-quantile plot. The figure design follows Figure 5.

Figure S6. Association signals for adult sitting height. $E M M A X$ associations between adult sitting height and 153,798 autosomal SNPs, considering the 133 individuals with sitting-height measurements available (Table S1). (A) Manhattan plot. (B) Quantile-quantile plot. The figure design follows Figure 5.

Figure S7. Association signals for adult subischial leg length. $E M M A X$ associations between adult subischial leg length and 153,798 autosomal SNPs, considering the 133 individuals with subischial leg length measurements available (Table S1). (A) Manhattan plot. (B) Quantile-quantile plot. The figure design follows Figure 5.

Figure S8. Genetic dataset preparation. Data filtering steps used to prepare the 406UNRELAT dataset used in all genetic analyses appear in the order in which they were applied. The numbers of SNPs or samples removed appear in red shaded boxes. SNPs/samples removed in one step were not subsequently considered.
