# CS111, Lecture 22 Dynamic Address Translation

#### **CS111 Topic 4: Virtual Memory**

<u>Virtual Memory</u> - How can one set of memory be shared among several processes? How can the operating system manage access to a limited amount of system memory?

**assign6:** implement *demand paging* system to translate addresses and load/store memory contents for programs as needed.

#### **Learning Goals**

- Understand the benefits of dynamic address translation
- Reason about the tradeoffs in different ways to implement dynamic address translation

#### **Plan For Today**

- Recap: virtual memory and dynamic address translation
- Approach #2: Multiple Segments
- Approach #3: Paging

#### **Plan For Today**

- Recap: virtual memory and dynamic address translation
- Approach #2: Multiple Segments
- Approach #3: Paging

## Virtual memory is a mechanism for multiple processes to simultaneously use system memory.

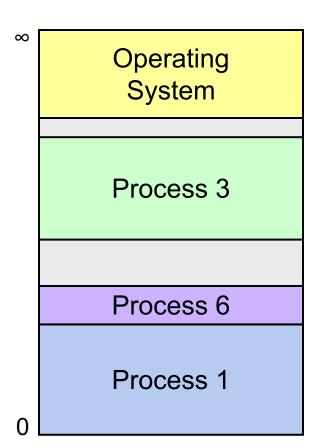

#### **Sharing Memory**

We want to allow multiple processes to simultaneously use system memory. Our goals are:

- Multitasking allow multiple processes to be memory-resident at once
- **Transparency** no process should need to know memory is shared. Each must run regardless of the number and/or locations of processes in memory.
- Isolation processes must not be able to corrupt each other
- Efficiency (both of CPU and memory) shouldn't be degraded badly by sharing

#### **Load-Time Relocation**

- When a process is loaded to run, place it in a designated memory space.
- That memory space is for everything for that process stack/data/code
- Interesting fact when a program is compiled, it is compiled assuming its memory starts at address 0. Therefore, we must update its addresses when we load it to match its real starting address.
- Use first-fit or best-fit allocation to manage available memory.
- Problems: isolation, deciding memory sizes in advance, fragmentation, updating addresses when loading

#### **Dynamic Address Translation**

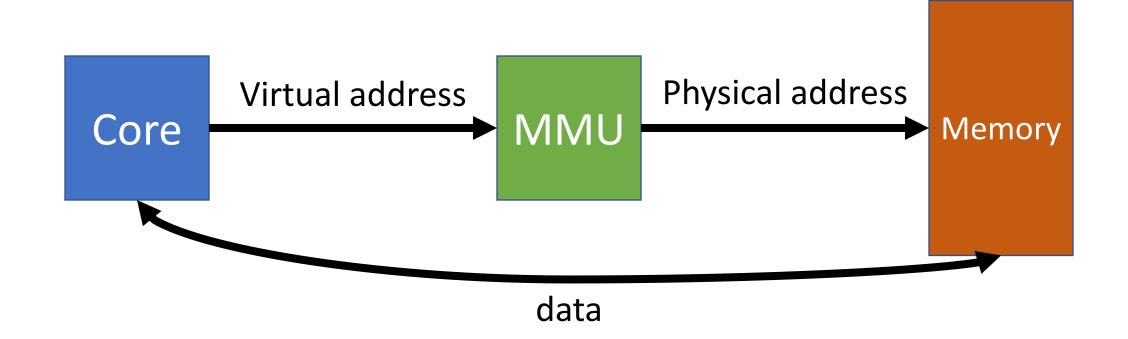

**Idea**: What if, instead of translating addresses when a program is loaded, the OS intercepted every memory reference and translated it?

- The OS can prohibit processes from accessing certain addresses (e.g. OS memory or another process's memory)
- Gives the OS lots of flexibility in managing memory
- Every process can now think that it is located starting at address 0 and is the only process in memory
- The OS will translate each process's address to the real one it's mapped to
- As a result, a process's virtual address space may look very different from how the memory is really laid out in the physical address space.

#### **Dynamic Address Translation**

We will add a *memory management unit* (MMU) in hardware that changes addresses dynamically during every memory reference.

- Virtual address is what the program sees
- Physical address is the actual location in memory

#### **Dynamic Address Translation**

**Key question:** how do the MMU / OS translate from virtual addresses to physical ones? Three designs we'll consider:

- 1. Base and bound
- 2. Multiple Segments
- 3. Paging

#### Approach #1: Base and Bound

- "base" is physical address starting point corresponds to virtual address 0
- "bound" is one greater than highest allowable virtual memory address
- Each process has own base/bound. Stored in PCB and loaded into two registers when running.

#### On each memory reference:

- Compare virtual address to bound, trap if >= (invalid memory reference)
- Otherwise, add base to virtual address to produce physical address

#### Approach #1: Base and Bound

- Key idea: each process appears to have a completely private memory whose size is determined by the bound register.
- The only physical address is in the base register, controlled by the OS. Process sees only virtual addresses!
- OS can update a process's base/bound if needed! E.g. it could move physical memory to a new location or increase bound.
- **Benefits**: inexpensive, little space needed, separation between virtual and physical addresses.
- **Drawbacks**: physical space must be contiguous, fragmentation, growth only upwards, no read-only region support

#### **Plan For Today**

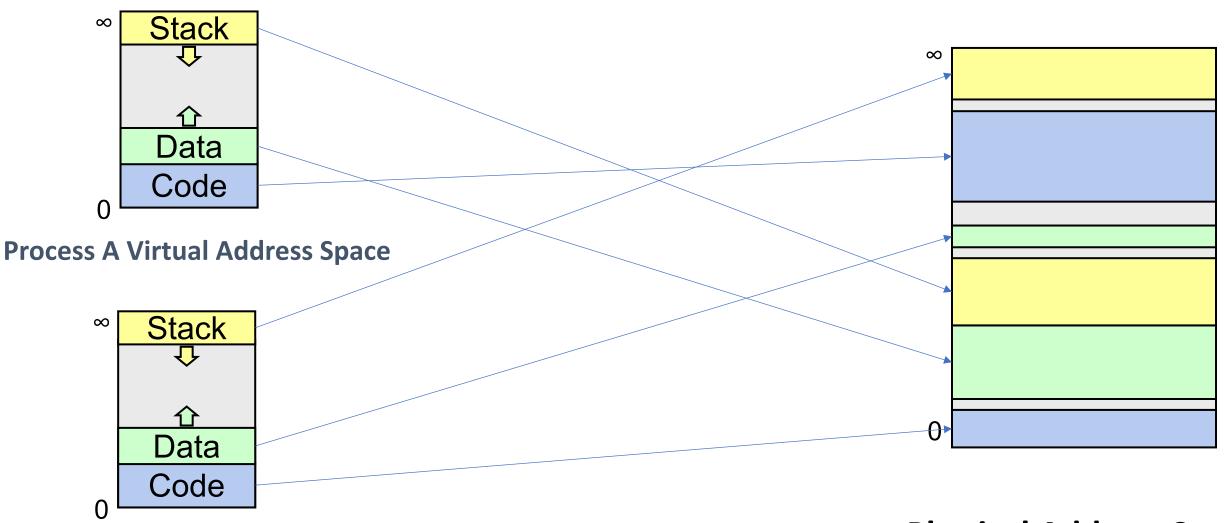

- Recap: virtual memory and dynamic address translation
- Approach #2: Multiple Segments
- Approach #3: Paging

## Idea: what if we broke up the virtual address space into segments and mapped each segment independently?

**Key Idea:** Each process is split among several variable-size areas of memory, called segments.

- E.g. one segment for code, one segment for data/heap, one segment for stack.
- The OS maps each segment individually each segment would have its own base and bound, and these are stored in a *segment map* for that process
- We can also store a *protection* bit for each segment; whether the process is allowed to write to it or not in addition to reading
- Now each segment can have its own permissions, grow/shrink independently, be swapped to disk independently, be moved independently, and even be shared between processes (e.g. shared code).

### **Multiple Segments**

**Process B Virtual Address Space** 

**Physical Address Space** 

#### On each memory reference:

- Look up info for the segment that address is in
- Compare virtual address to that segment's bound, trap if >= (invalid memory reference)
- Add segment's base to virtual address to produce physical address

Problem: how do we know which segment a virtual address is in?

Problem: how do we know which segment a virtual address is in?

One Idea: make virtual addresses such that the top bits of the address specify its segment, and the low bits of the address specify the offset in that segment.

Virtual Address	
0x122	0x456
Segment #	Offset

Example: PDP-10 computer had design with 2 segments, and the most-significant bit in addresses encoded which one was being referenced.

Another possibility: deduce from machine code instruction executing

#### What are some benefits of this approach?

- Flexibility can manage each segment independently
- Can share segments between processes
- Can move segments to compact memory and eliminate fragmentation

#### What are some drawbacks of this approach?

- Variable-length segments result in memory fragmentation can move, but creates friction
- Typically small number of segments
- Encoding segment + offset rigidly divides virtual addresses (how many bits for segment vs. how many for offset?)

## Idea: what if we broke up the virtual address space not into variable-length segments, but into fixedsize chunks?

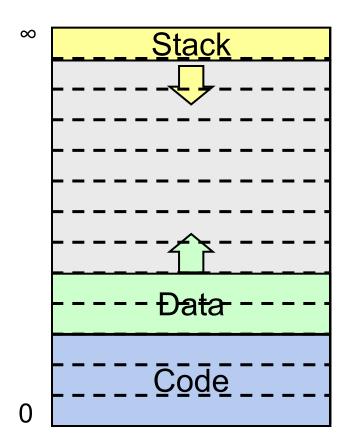

#### **Plan For Today**

- Recap: virtual memory and dynamic address translation
- Approach #2: Multiple Segments
- Approach #3: Paging

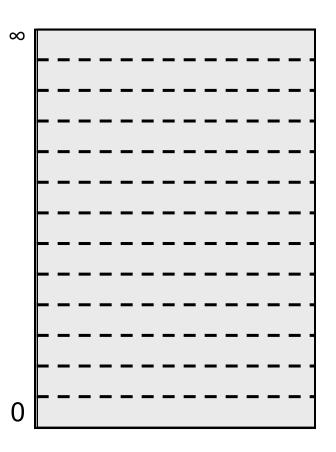

#### Approach #3: Paging

**Key Idea:** Each process's virtual (and physical) memory is divided into fixed-size chunks called *pages*. (Common size is 4KB pages).

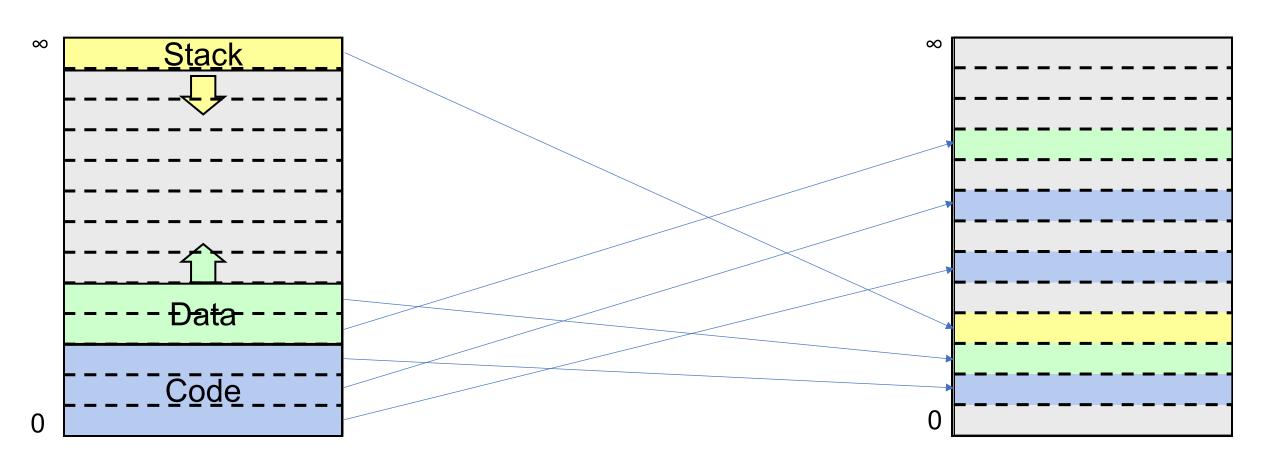

- A "page" of virtual memory maps to a "page" of physical memory. No partial pages
- The **page number** is a numerical ID for a page. We have virtual page numbers and physical page numbers.
- A virtual address is comprised of the virtual page # and offset in that page.
- A physical address is comprised of the physical page # and offset in that page.

**Process A Virtual Address Space** 

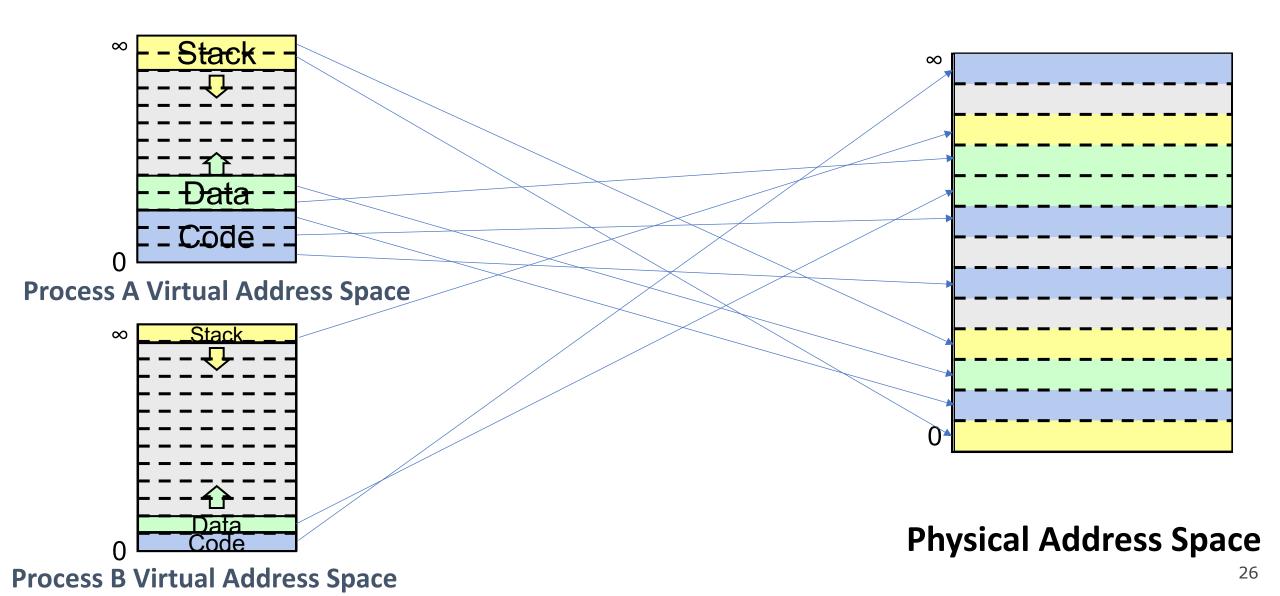

**Physical Address Space** 

**Process A Virtual Address Space** 

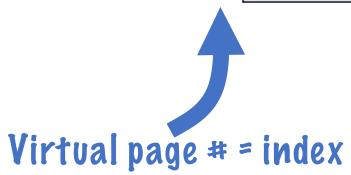

**Physical Address Space** 

How do we track, for a given process, which virtual page maps to which physical page?

Each process has a page map ("page table") with an entry for each virtual page, mapping it to a physical page number and other info such as a protection bit (read-only or read-write).

<u>Index</u>	Physical page #	Writeable?

Virtual page #

**Physical Address** 

<u>Index</u>	Physical page #	Writeable?
•••	•••	•••
3	0x2342	1
2	0x12625	1

For 4KB pages (4096 bytes), the offset can be 0-4095. Thus, we can store the offset in 12 bits (the amount needed to represent any number 0-4095). 12 bits = 3 hexadecimal digits.

x86-64 with 4KB pages has 36-bit virtual page numbers and 40-bit physical page numbers.

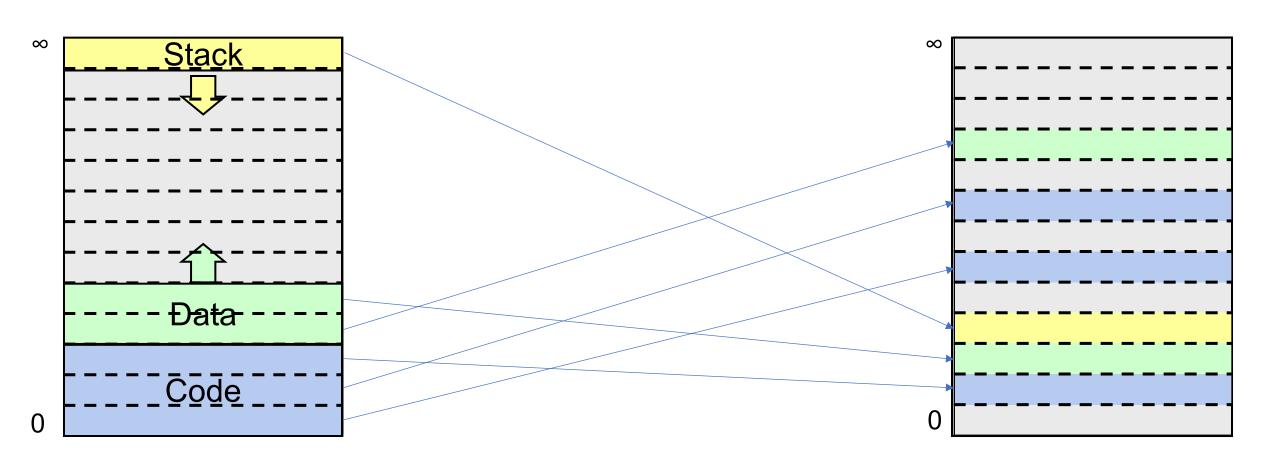

### **Paging**

How do we provide memory to a process?

- Keep a global free list of physical pages grab the first one when we need one
- Update process page table for a virtual page to map to this physical page, and mark present / set permission bit

In this way, we can represent a process's segments (e.g. code, data) as a collection of 1 or more pages, starting on any page boundary.

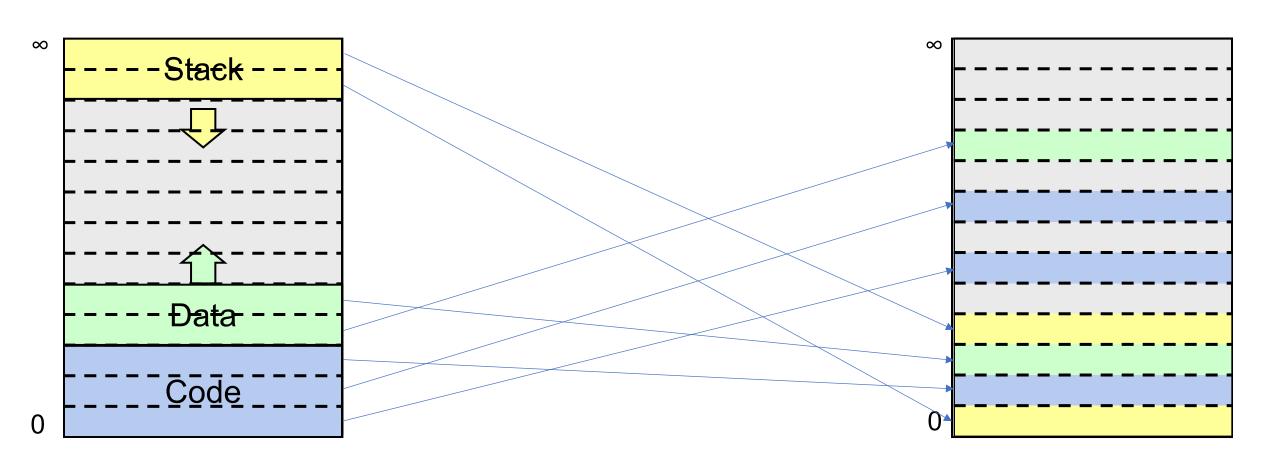

# Requesting More Memory

**Process A Virtual Address Space** 

**Physical Address Space** 

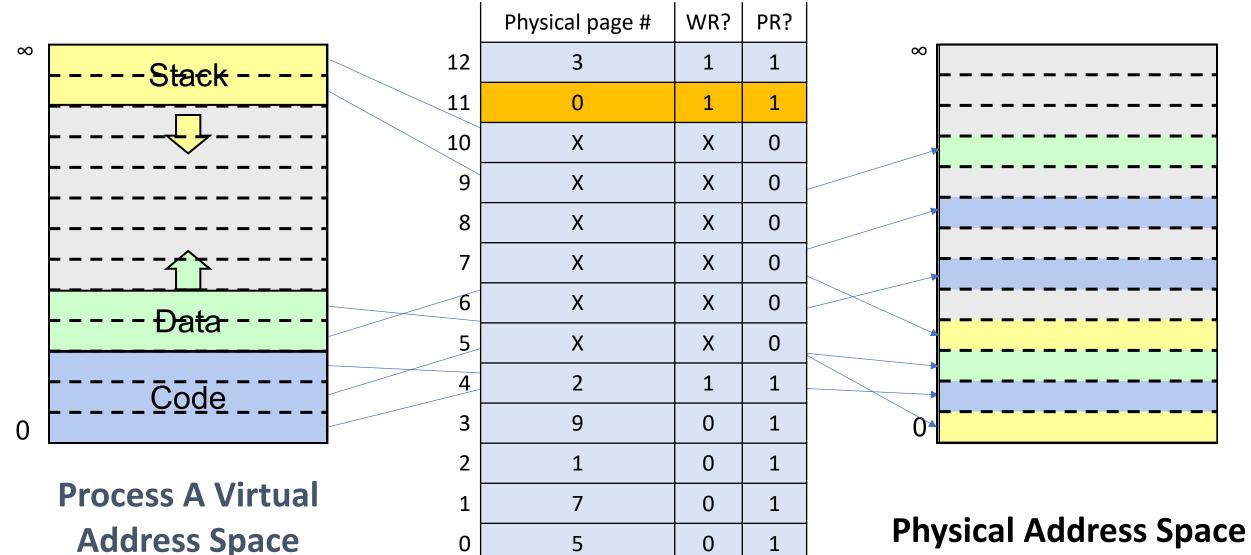

### **Requesting More Memory**

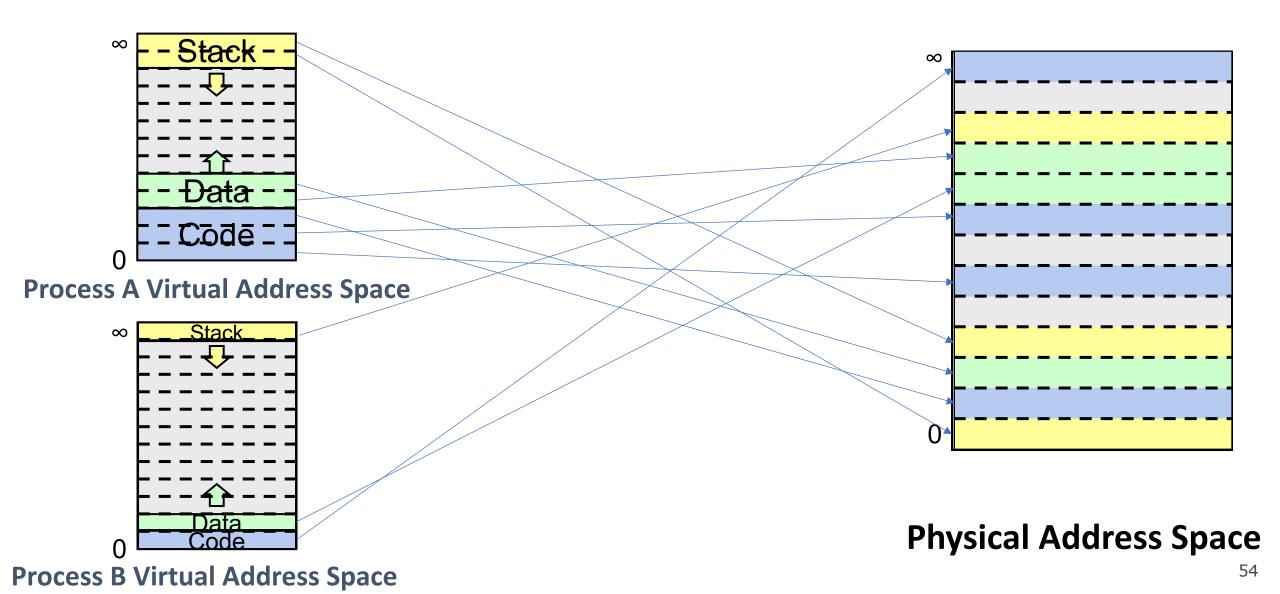

**Process A Virtual Address Space** 

**Physical Address Space** 

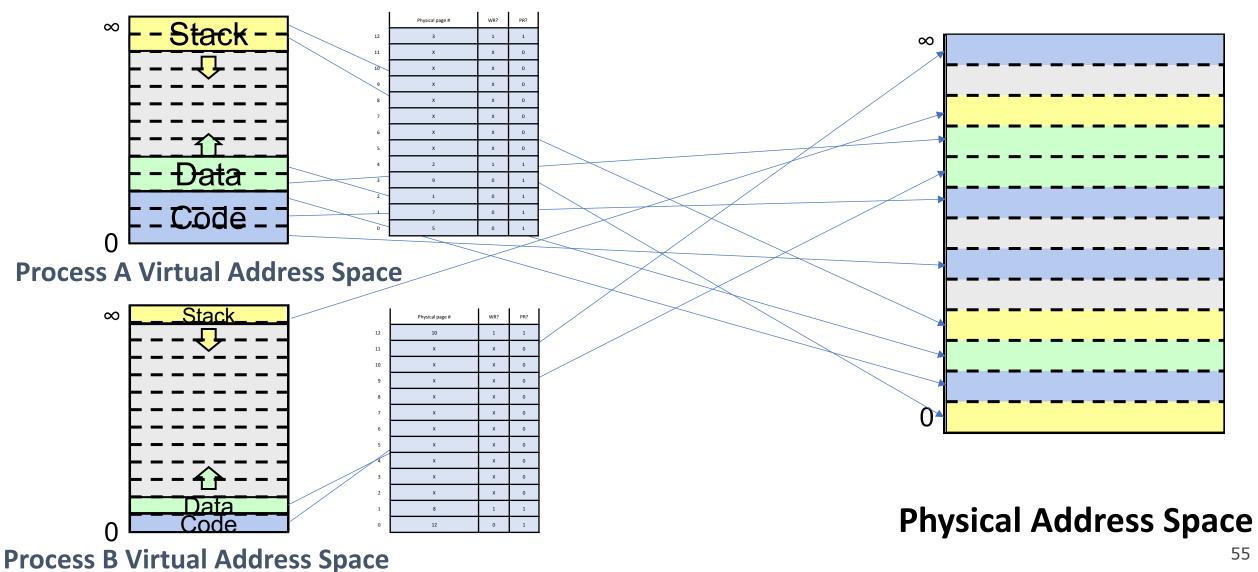

#### Requesting More Memory

# **Paging**

#### Each Process Has A Page Map

# **Paging**

On each memory reference:

- Look up info for that virtual page in the page map
- If it's a valid virtual page number, get the physical page number it maps to, and combine it with the specified offset to produce the physical address.

**Problem:** what about invalid page numbers? I.e. how do we know/represent which pages are valid or invalid?

**Solution:** have entries in the page map for *all* pages, including invalid ones. Add an additional field marking whether it's valid ("present").

#### Recap

- Recap: virtual memory and dynamic address translation
- Approach #2: Multiple Segments
- Approach #3: Paging

Next time: demand paging

#### Lecture 22 takeaway:

Dynamic Address translation means that the OS intercepts and translates each memory access. Initial approaches to this include base+bound per process, or expanding that to be base+bound per variablelength segment, or instead dividing into fixed-size pages.
