Conductance fluctuations in GaAs quantum dots with spin-orbit and Zeeman coupling are investigated experimentally and compared to a random matrix theory formulation that defines a number of regimes of spin symmetry depending on experimental parameters. Accounting for orbital coupling of the in-plane magnetic field, which can break time-reversal symmetry, yields excellent overall agreement between experiment and theory.

DOI: 10.1103/PhysRevB.72.081305

The combination of confinement, spin-orbit (SO) coupling, and Zeeman splitting in semiconductor quantum dots gives rise to rich physics, including experimental access to interesting partially broken spin symmetries\(^1\) and a suppression of SO effects due to confinement\(^1\)–\(^5\) that provides long spin lifetimes in small quantum dots.\(^6\) Further consequences of these combined effects are that the confinement-induced suppression of SO effects is lifted by adding a Zeeman field\(^1\)–\(^3\) or by allowing spatial dependence of the SO coupling.\(^7\) Because of the finite thickness of a two-dimensional electron gas (2DEG), an in-plane magnetic field \(B_r\) will have an orbital coupling that affects the electron dispersion and can break time-reversal symmetry\(^4,8–12\) (TRS), adding additional complexity to this system.

This paper presents an experimental study of mesoscopic conductance fluctuations in quantum dots that possess both significant SO and Zeeman coupling. We find that the \(B_r\) dependence of the variance of conductance fluctuations, \(\text{var} g\), with TRS explicitly broken by a perpendicular field \([B_y \neq 0, \text{i.e.,} B_r \gg \hbar/(eA)\], where \(A\) is the dot area\) depends critically on the strength of SO coupling and dot size. This dependence can be understood in terms of spin symmetries partially broken by \(B_r\) and in quantitative agreement with an appropriate random matrix theory (RMT) formulation.\(^1\)\(^,\)\(^2\)\(^,\)\(^4\)\(^,\)\(^12\) We also find that \(\text{var} g(B_y, B_r)\) becomes independent of \(B_r\) at large \(B_r\) due to \(B_r\) breaking TRS, consistent with previous results.\(^4,10\) Taking into account orbital coupling,\(^8,9\) agreement between theory and experiment is excellent for both broken and unbroken TRS and various regimes of spin symmetry.

In quantum dots, the effects of Rashba and linear Dresselhaus SO coupling are suppressed due to confinement in the absence of Zeeman coupling.\(^1,2,5\) For large Zeeman splitting or weak confinement, this suppression is lifted and symmetry classes with partially broken spin symmetry appear. A RMT analysis of this system was developed by Aleiner et al.\(^1\) and extended to include inhomogeneous SO coupling and interpolation between ensembles.\(^1\) The RMT formulation identifies three symmetry parameters that govern the amplitude (variance) of conductance fluctuations, \(\text{var} g \propto s/(\beta \Sigma)\). Here, \(\beta = \{1,2,4\}\) is the usual D’yakonov parameter reflecting TRS, \(s = \{1,2\}\) accounts for Kramers degeneracy, and \(\Sigma = \{1,2\}\) characterizes mixing between Kramers pairs. With these parameters, spin symmetry may be either unbroken \((s = 2, \Sigma = 1)\), partially broken \((s = 1, \Sigma = 1)\), or fully broken \((s = 1, \Sigma = 2)\), causing a reduction of the variance by a factor of 2 each time spin symmetry is incrementally broken. Temperature and decoherence also reduce \(g\), but ratios such as \(\text{var} g(B_r) / \text{var} g(B_r = 0)\) are affected only weakly.

Conductance fluctuations are known to be reduced by SO and Zeeman coupling in bulk (disordered) mesoscopic samples, and theories\(^13–15\) are in good agreement with experiments.\(^16\) Recently, the combined effects of SO and Zeeman coupling on magnetoresistance in bulk samples were investigated,\(^11\) and spin-induced breaking of TRS was reported.\(^12\) Partially broken spin symmetry has been theoretically predicted.\(^1,14\) The results of Ref. 1 were used to explain the existing data on \(\text{var} g(B_y, B_r)\) (Ref. 3) as well as subsequent experiments on average conductance (weak localization and antilocalization) in quantum dots.\(^4,17\)

Four gate-defined quantum dots of various sizes on two heterostructure wafers were measured (see Table I and Figs. 1 and 2 insets). The lower-density wafer showed weak localization,\(^10\) while the higher-density material has sufficient SO coupling to exhibit antilocalization at \(B_r = 0\) (Ref. 4). Further details of these wafers are given in Refs. 4 and 10. Measurements were made in a \(^3\)He cryostat at 0.3 K using a current bias of 1 nA at 338 Hz. In order to apply tesla scale \(B_y\) while maintaining subgauss control of \(B_y\), we mount the sample with the 2DEG aligned to the axis of the primary solenoid (accurate to \(\sim 1^\circ\)) and use an independent split-coil magnet attached to the cryostat to provide \(B_r\).\(^3\) The Hall voltage measured in a comounted Hall bar sample as well as the symmetry of transport through the dot itself...
FIG. 1. Conductance average \( \left\langle g(B_{\perp}) \right\rangle \) (solid dots) and variance \( \text{var} \ g(B_{\perp}) \) (open circles and squares) as a function of perpendicular magnetic field \( B_{\perp} \) with \( B_{\parallel}=0 \), for large and small dots on the high-density material, at \( T=300 \) mK. (a) Antilocalization in \( \left\langle g(B_{\perp}) \right\rangle \) for the 8-\( \mu m^2 \) dot. (b) Weak localization in \( \left\langle g(B_{\perp}) \right\rangle \) for the 1.2-\( \mu m^2 \) dot, demonstrating confinement suppression of SO effects. Both dots show an enhancement of \( \text{var} \ g \) at \( B_{\perp}=0 \). Fits of RMT (Ref. 1) to \( \left\langle g(B_{\perp}) \right\rangle \) (dashed curves) and \( \text{var} \ g(B_{\perp}) \) (solid curves) using fit parameters determined from fits to \( \left\langle g \right\rangle \) plus an overall scale factor for \( \text{var} \ g \) (see text). The insets show device micrographs.

(Visible for \( B_{\parallel} \leq 2T \)) was used to locate \( B_{\perp}=0 \) as it changed with \( B_{\parallel} \).

Statistics of conductance fluctuations were gathered using two shape-distorting gates\(^{18} \) while the point contacts were actively held at one fully transmitting mode each. At each value of \( B_{\perp} \) and \( B_{\parallel} \), mean and variance were estimated based on \( \sim 400 \) (\( \sim 200 \)) statistically independent samples for the low-density (high-density) dots. For \( \text{var} \ g(B_{\perp}, B_{\parallel} \neq 0) \) data with TRS explicitly broken, \( B_{\parallel} \) was used to gather additional samples to reduce the statistical error.

Fitting the RMT results to \( \left\langle g(B_{\perp}) \right\rangle \) yields values for the average SO length \( \lambda_{so} = \sqrt{\left| \lambda_{1} \lambda_{2} \right|} \), where \( \lambda_{1,2} \) are the SO lengths along the main crystal axes, as well as the phase coherence time \( \tau_{\phi} \) and a geometrical parameter \( \kappa_{\perp} \). The SO inhomogeneity \( \nu_{so} = \sqrt{\lambda_{1}/\lambda_{2}} \) can be extracted from \( \left\langle g(B_{\perp}) \right\rangle \) in the presence of antilocalization (AL), and is taken as \( \nu_{so} \).

TABLE I. Carrier density \( n \), dot area \( A=L^2 \), coherence time \( \tau_{\phi} \), spin-orbit parameters \( \lambda_{so} \) and \( \nu_{so} \), RMT parameters \( \kappa_{\perp} \), \( f_{\text{var}} \), and \( \xi \), and FJ parameters \( a \) and \( b \) (see text).

FIG. 3. Variance of conductance fluctuations, \( \text{var } g \), in high-density dots, as a function of in-plane field \( B_\parallel \), with \( B_\perp \neq 0 \) sufficient to break TRS (open symbols) and \( B_\perp = 0 \) (solid symbols). The big dot shows less reduction in var \( g(B_\parallel \neq 0) \) with \( B_\parallel \) than the small dot, consistent with RMT (see text). The insets show quantum correction to average conductance, \( \delta g(B_\parallel) = (g(B_\parallel = 0, B_\perp)) - (g(B_\parallel \neq 0, B_\perp)) \). In both main figure and insets, dashed curves are fits to RMT, solid curves (labeled RMT+FJ) are fits to RMT including orbital coupling of \( B_\parallel \) (see text).

FIG. 4. As in Fig. 3, but for low-density dots. In this case, both dots have a reduction factor \( R \sim 4 \) in parallel field, consistent with RMT (curves). Orbital coupling of \( B_\parallel \) breaks TRS, making var \( g \) independent of \( B_\perp \) and quenching the quantum correction to average conductance, \( \delta g \rightarrow 0 \) (insets) on the same (dot-size-dependent) scale of \( B_\parallel \).

with AL and WL), var \( g \) at \( B_\perp = 0 \) is reduced upon application of a TRS-breaking perpendicular field, as seen in Figs. 1 and 2. This effect has been investigated previously for the weak SO (WL) case,\(^{18,20}\) and has been observed but not analyzed for the strong SO (AL) case.\(^4\) The solid theory curves in Figs. 1 and 2 include thermal smearing and decoherence effects and use parameters obtained from fits of RMT to \( \langle g(B_\perp) \rangle \), plus one additional parameter, \( f_{\text{cor}} \) (Table 1) to normalize the var \( g(B_\perp \neq 0) \) the RMT value. This factor compensates the assumption of multimode leads, \( N \gg 1 \), in the RMT,\(^1\) whereas the experiment has \( N = 2 \). RMT for var \( g \) in the \( N = 2 \) case has been given, but does not include SO or Zeeman terms.\(^21\)

We next investigate the effect of an in-plane magnetic field on var \( g \), focusing first on the case where TRS is broken by a small perpendicular field, \( B_\perp \neq 0 \). As seen in Figs. 3 and 4, var \( g(B_\perp \neq 0, B_\parallel) \) decreases with increasing \( B_\parallel \) and saturates at large \( B_\parallel \), giving reduction factors \( R = \text{var } g(B_\perp \neq 0, B_\parallel = 0)/\text{var } g(B_\perp \neq 0, B_\parallel > 0) \) between \( R \sim 1.6 \) for the large high-density dots (which show AL at \( B_\parallel = 0 \)) and \( R \sim 4 \) for large low-density dots (which show WL at \( B_\parallel = 0 \)). This range of values for \( R \) can be readily interpreted within RMT: For the large high-density dot (relatively strong SO coupling, not suppressed by confinement), Kramers degeneracy is broken whenever TRS is broken, and there is weak spin mixing \((\beta = 2, s = 1, 1 < \Sigma < 2)\) at \( B_\parallel = 0 \). The effect of \( B_\parallel \) is to fully mix the Kramers pair \((\beta = 2, s = 1, \Sigma = 1)\), thus the reduction \( 1 \leq R \leq 2 \). On the other hand, dots showing WL at \( B_\parallel = 0 \) retain spin degeneracy \((\beta = 2, s = 2, \Sigma = 2)\) at \( B_\parallel = 0 \), which is then lifted by Zeeman coupling \((\beta = 2, s = 1, \Sigma = 2)\) and mixed at larger \( B_\parallel \) due to SO coupling.

Spin mixing induced by \( B_\parallel \), marking the \( \Sigma = 1 \) to 2 crossover, occurs when a field-dependent energy scale \( \tilde{\xi}^2 \) exceeds the level broadening \( \tilde{\gamma} = h / (\tilde{\tau}_{\text{esc}}^+ + \tilde{\tau}_{\text{esc}}^-)^{-1} \) \((\tilde{\tau}_{\text{esc}}^+ = N \Delta / h) \) is the escape rate from the dot). This new energy scale depends on both Zeeman and SO coupling, \( \tilde{\xi}^2 = \tilde{\gamma} / (2E_F)(A/\lambda_{\text{so}}^2) \), where \( \tilde{\gamma} = g \mu_B B \) is the Zeeman splitting, \( E_F \) is the Thouless energy (for ballistic dots \( E_T \sim h v_F / \Delta \)), \( v_F \) is the Fermi velocity, and \( \xi \) is a parameter of order one that depends on dot geometry as well as the direction of \( B_\parallel \).\(^{1,2} \) Note that \( \tilde{\xi}^2 / \tilde{\gamma} = \tilde{\xi}^3 A^{3/2} \) (when \( \tilde{\tau}_{\text{esc}} \ll \tilde{\tau}_\text{slow} \) so that the \( \Sigma = 1 \) to 2 crossover field will depend on dot size. For the smallest dot, the crossover is inaccessible, \( \Sigma = 1 \) for all measured fields and \( R \sim 2 \) due to breaking of Kramers degeneracy only \((s = 2 \rightarrow 1)\). In the low-density dots, the \( \Sigma = 1 \) to 2 crossover is accessible, occurring around \( B_\parallel \sim 1 \) (3) T for the larger (smaller) dot. The large high-density dot has \( 1 < \Sigma < 2 \) already at \( B_\parallel = 0 \) due to SO coupling, and the crossover to \( \Sigma = 2 \) occurs around \( B_\parallel \sim 3 \) T. Because of the undetermined coefficient \( \xi \), the SO
length $\lambda_p$ cannot be independently extracted from var $g(B_i)$. Taking $\xi$ as a single fit parameter, the dashed curves in Figs. 3 and 4 give the RMT results, which are in good agreement with experiment for all devices.

Finally, we investigate orbital effects of $B_i$ on var $g$, measured when TRS is not explicitly broken by a perpendicular field ($B_i = 0$). Figures 3 and 4 show that as $B_i$ is increased, var $g(B_i = 0, B_i)$ decreases sharply, approaching var $g(B_i \neq 0, B_i)$. At large $B_i$, var $g$ becomes independent of $B_i$, whereas RMT gives var $g_{RMT}(B_i = 0)/var g_{RMT}(B_i \neq 0) = 2$ for all $B_i$. On a similar scale of $B_i$, WL corrections $\delta g(B_i) = (g(B_i = 0, B_i)) - (g(B_i \neq 0, B_i))$ are also vanishing in all devices whereas RMT predicts a finite $\delta g$. As discussed previously, these effects result from the breaking of TRS by $B_i$.\(^{5,9}\)

Following Fal’ko and Jungwirth\(^{8}\) (FJ) we account for the suppression of $\delta g(B_i)$ and var $g(B_i)$ by introducing a field-dependent factor $f_{f_{j}}(B_i) = (1 + \tau_{B_i}^{-1} / \tau_{c})^{-1}$, where $\tau_{B_i}^{-1} = aB_i^2 + bB_i^0$. The $B_i^2$ term reflects interface roughness and dopant inhomogeneities. The $B_i^0$ term is due to the asymmetry of the well. The RMT results are then modified as $\delta g(B_i) = \delta g_{RMT}(B_i)f_{f_{j}}(B_i)$ and var $g(B_i = 0, B_i) = var g_{RMT}(B_i \neq 0, B_i) \tau_{B_i}^{-1} + f_{f_{j}}(B_i)$ to account for flux effects of the parallel field.\(^{9,10,22}\) The coefficient $a$ is obtained from a fit to the experimental $\delta g(B_i)$ while $b$ is estimated from device simulations.\(^{22}\) (Table I). The resulting theory curves for both $\delta g(B_i)$ (solid curves, insets in Figs. 3 and 4) and var $g(B_i = 0, B_i)$ (solid curves, main panels) are in good agreement with experiment. We emphasize that the theoretical variance curves var $g(B_i = 0, B_i)$ are not fitted to the data. Estimates of $a, b$ based on correlation functions of parallel-field conductance fluctuations\(^{10}\) are consistent with the values obtained here based on $\delta g(B_i)$.

In summary, mesoscopic conductance fluctuations in open quantum dots in the presence of SO coupling and in-plane fields can be understood in terms of fundamental symmetries in the system, including observed partially broken spin rotation symmetries as well as time-reversal symmetry, which can be broken by both perpendicular and in-plane fields.
