Crystal structure of the natural anionconducting channelrhodopsin *Gt*ACR1

Yoon Seok Kim^{1,9}, Hideaki E. Kato^{2,3,9}*, Keitaro Yamashita⁴, Shota Ito⁵, Keiichi Inoue^{3,5,6}, Charu Ramakrishnan¹, Lief E. Fenno¹, Kathryn E. Evans¹, Joseph M. Paggi^{7,8}, Ron O. Dror^{7,8}, Hideki Kandori^{5,6}, Brian K. Kobilka² & Karl Deisseroth¹*

The naturally occurring channelrhodopsin variant anion channelrhodopsin-1 (ACR1), discovered in the cryptophyte algae *Guillardia theta*, exhibits large light-gated anion conductance and high anion selectivity when expressed in heterologous settings, properties that support its use as an optogenetic tool to inhibit neuronal firing with light. However, molecular insight into ACR1 is lacking owing to the absence of structural information underlying light-gated anion conductance. Here we present the crystal structure of *G. theta* ACR1 at 2.9 Å resolution. The structure reveals unusual architectural features that span the extracellular domain, retinal-binding pocket, Schiff-base region, and anion-conduction pathway. Together with electrophysiological and spectroscopic analyses, these findings reveal the fundamental molecular basis of naturally occurring light-gated anion conductance, and provide a framework for designing the next generation of optogenetic tools.

Most organisms depend on light for energy and information. Motile organisms typically capture light using rhodopsin proteins, largely classified into two groups: microbial (type I) and animal (type II)^{1,2}, both exhibiting seven-transmembrane helices and a retinal-based chromophore, but with different effector mechanisms. Animal rhodopsins primarily work as G-protein-coupled receptors that recruit second-ary messengers to control effectors such as ion channels that modulate cellular activity, whereas channel and pump microbial rhodopsins can directly provide effector functionality as transmembrane current^{1,2}. Heterologous expression of single-component microbial opsin genes targeted to specific cells of animals defines an experimental approach (optogenetics³) for biology, enabling control of specific cells in behaving organisms with light.

Both channel and pump-encoding opsins are established in optogenetics. Variants of the channel subtype (cation-conducting channelrhodopsins, CCRs) elicit light-triggered cation currents (usually excitatory in neurons). Indeed, light-triggered cation currents are excitatory in the natural host as well; plant behaviours initially observed by botanists more than 150 years ago (movement of single-celled algae excited by light)⁴ were later found to be due to CCRs, with the initially known member of this subclass (*Chlamydomonas reinhardtii* ChR1) identified as a cation channel in 2002⁵. Many CCRs have been discovered or designed^{5–14}, and currently available CCRs offer a palette of diversity in absorption spectrum, photocurrent magnitude, light sensitivity and on/off-kinetics^{12,15}.

The development of inhibitory optogenetics initially lagged, but has made strides in recent years^{3,4,16}. Light-induced neuronal inhibition with microbial opsins was first achieved with inward Cl⁻ pumps and outward H⁺ pumps such as *Natronomonas pharaonis* halorhodopsin (*Np*HR) and archaerhodopsin-3 (AR3)^{17,18}. Although widely used, these pumps move only one ion per photon (versus hundreds for channels), thereby exhibiting reduced efficacy^{15,16}. In 2014, anion-conducting channelrhodopsins (ACRs) were created^{19,20} on the CCR backbone, guided by structural modelling; subsequently, in 2015,

naturally occurring ACRs were isolated from chlorophyte algae²¹ (*Gt*ACR1 and *Gt*ACR2). The designed ACRs have been developed further^{22–24}, and additional natural ACRs have been found by genome mining^{25–27}. ACRs can translocate 10⁴–10⁵ ions per second²¹ and can exhibit 10²–10⁴-fold higher light sensitivity than inhibitory pumps^{19–21}. After the first demonstration in 2015 of ACRs as inhibitory optogenetic tools that could successfully modulate animal behaviour (with a designed ACR called iC++²²), both ACR classes have been widely applied in mice, flies and fish^{22,23,28–30}.

Despite progress in ACR-based inhibitory optogenetics, little is known about the structural basis of radically different ion-selectivity involved in anion conduction. Homology models of *Gt*ACR1 were built^{27,31-33} using the structure of the C1C2 CCR³⁴, but precise structural information on ACRs remained completely lacking. A high-resolution crystal structure would be beneficial, not only to enhance fundamental understanding, but also to provide a foundation for expanding the toolbox of optogenetics (as rapidly resulted from the first CCR crystal structure³⁴ in 2012).

Here we obtain and characterize the crystal structure for GtACR1 at 2.9 Å resolution. This information, together with electrophysiological and spectroscopic analyses, revealed unique natural ACR structure–function relationships that span the extracellular domain, retinal-binding pocket, Schiff base region, and anion-conduction pathway. These features advance our understanding of natural channelrhodopsin biology, and reveal a path for the design and creation of new tools for optogenetics.

Structure determination

To understand the structural basis of light-activated anion conduction, we purified (Extended Data Fig. 1a) and crystallized the best-characterized natural ACR, *Gt*ACR1. To improve crystallizability, we truncated 13 C-terminal residues; the resulting construct (residues 1–282) showed similar photocurrents to full-length *Gt*ACR1 in human HEK293 cells (Extended Data Fig. 1b) and robust expression in neurons (Extended

Data Fig. 1c). Crystals were obtained by lipidic cubic phase analysis (Extended Data Fig. 1d); the structure was determined by molecular replacement, using coordinates of C1C2 (Protein Data Bank accession 3UG9)³⁴, and refined to 2.9 Å resolution (Extended Data Fig. 2).

Crystals belonged to the P21 space group, containing four GtACR1 protomers (chains A-D) in the asymmetric unit (Extended Data Fig. 1e). Chains A/B and chains C/D were each associated as dimers, with the two dimer molecules arranged anti-parallel. Each protomer showed almost identical conformation except for orientation of certain residues facing the membrane (for example, Trp150, Phe168, Tyr201 and Leu232; Extended Data Fig. 1f), with a notable C-terminal difference. Although the C termini of chains B/C were ordered until Pro273 with similar conformations, those of chains A/D were ordered until Asp278 and Glu280, respectively, and the last 6-8 residues exhibited completely different conformations (Extended Data Fig. 1g). Except for the disordered 3 N-terminal and 2-9 C-terminal residues, GtACR1 itself (residues 4-278 in chain A, 4-273 in chain B, 4-273 in chain C, and 4-280 in chain D), all-trans retinal (ATR), 5 lipids and 4 water molecules were all clearly resolved in the electron density map (Extended Data Fig. 2).

GtACR1 structure and comparison with C1C2 and CrChR2

GtACR1 exhibits a unique N-terminal extracellular domain (residues 4–29), a 7-transmembrane domain (residues 30–249), and a C-terminal region (residues 250–280) (Fig. 1). In comparing GtACR1 with the CCRs C1C2 (PDB accessions 3UG9 and 4YZI)^{13,34} and CrChR2³⁵, we observed both similarities (despite relatively low sequence identities of 28% and 27%, respectively; Extended Data Fig. 3) and notable distinctions. Although there were aspects of architectural commonality between GtACR1 and C1C2 dimers and between GtACR1 and CrChR2 dimers (root mean square deviation (r.m.s.d.) values of 2.10 Å and 1.87 Å respectively over all C_α atoms), and between corresponding monomers (r.m.s.d. values of 1.62 Å and 1.39 Å), many crucial differences with GtACR1 were apparent (Fig. 2a, b).

First, although transmembrane helix 7 (TM7) of C1C2–*Cr*ChR2 protrudes approximately 18 Å from the membrane and its following C-terminal region exhibits a β -sheet (Fig. 2a, b), TM7 of *Gt*ACR1 does not protrude (resembling more pump-type rhodopsins such as bacteriorhodopsin and halorhodopsin) (Extended Data Fig. 4) and its C-terminal region displays a random coil (Fig. 2a, b; Extended Data Fig. 1g); although lacking secondary structure, this region has several hydrogen-bonding interactions with TM5, TM6, intracellular loop 2 (ICL2) and ICL3, and thus could be important in assembly/structural integrity (Extended Data Fig. 5a). To test this, we truncated the corresponding 29 residues from *Gt*ACR1 as crystallized; this almost abolished expression, consistent with the prediction that the C terminus is important for folding and/or stability (Extended Data Fig. 5b).

Second, the N-terminal domain of *Gt*ACR1 has a short helix– loop–helix forming hydrogen-bonding interactions with extracellular

Fig. 2 | **Structural comparison of** *Gt***ACR1 with C1C2. a**, **b**, Side (left) and extracellular (right) view of *Gt***ACR1** (blue) superimposed onto C1C2 (green) (**a**), and *Cr*ChR2 (yellow) (**b**). Red arrows mark the differences between the structures. **c**, Magnified view of N termini of *Gt***ACR1**, C1C2 and *Cr*ChR2 as delimited by orange boxes in **a** and **b**. Green sticks denote disulfide bonds; note intramolecular disulfides bonds in *Gt***ACR1** (C219-to-C21) compared to the exclusively intermolecular disulfide bonds in C1C2 (at C73, C75, and C66) and *Cr*ChR2 (at C34 and C36).

loop 1 (ECL1) (Extended Data Fig. 5c), whereas that of C1C2 has three helices and two β-strands, tethered to ECL1 via both hydrogen bonding and a Zn²⁺ ion¹³. Notably, C1C2, CrChR2 and GtACR1 all have several (2-3) N-terminal cysteine residues, but with different positions and functions. Cys66, Cys73 and Cys75 of C1C2, and Cys34 and Cys36 of CrChR2 form three and two intermolecular disulfide bridges respectively (Fig. 2c). Previous studies had predicted that the residue corresponding to Cys73 in C1C2 (Cys34 in CrChR2) would be Cys21 in GtACR1²⁶ and would form an intermolecular disulfide bridge³². However, the GtACR1 structure revealed that Cys21 forms not an intermolecular, but instead a new intramolecular, disulfide bridge with Cys219 on ECL3, whereas Cys6 forms an intermolecular disulfide bridge (Figs. 1, 2c). Gel-filtration chromatography and SDS-PAGE (Extended Data Fig. 5d, e) further support the conclusion that Cys21 and Cys219 are more important for folding and expression, and Cys6 for dimerization.

Third, ICL2 of *Gt*ACR1 has a β -sheet that is unique among microbial rhodopsins, extending from the protein core (Fig. 2a, b), in contrast to ICL2 of the C1C2–*Cr*ChR2 dimer, which is a random coil close to the protein core involved in dimerization³⁴. Notably, because of these differences in the N terminus and ICL2, the interface area of the *Gt*ACR1 dimer (1,315 Å²) is smaller than that for the C1C2 (2,027 Å²) or *Cr*ChR2 (1,688 Å²) dimers (Extended Data Fig. 5f–h). This property is concordant with our finding that loss of the intermolecular disulfide bridge markedly affects *Gt*ACR1 dimerization in SDS–PAGE analysis (Extended Data Fig. 5e), whereas the loss of the disulfide in C1C2–*Cr*ChR2 has minimal effect on dimerization^{36–38}.

Finally, we note a feature of overall *Gt*ACR1 structure; the extracellular ends of TM1/TM2 are notably tilted compared to those of CCRs (Fig. 2a, b). These tilts remodel the extracellular vestibule, forming a novel ion-conducting pathway. This unanticipated structural feature appears of substantial importance for understanding the unique ion-conduction properties of *Gt*ACR1 (below).

Retinal-binding pocket

In all rhodopsins, retinal is covalently bound to a TM7 lysine residue, forming the Schiff base. *Gt*ACR1 and C1C2 contain similar configurations of all-*trans*-retinal and 15-*anti*-retinal^{34,39,40} (Fig. 2a). Here we focus on comparison with C1C2, because the 2017 *Cr*ChR2 CCR structure was almost identical to the well-studied 2012 C1C2 CCR structure (Extended Data Fig. 4c; r.m.s.d. value of 0.82 Å over all C_{α} atoms), and was also reported as a mixture of two states D480 and D470

Fig. 3 | **RBP of** *Gt***ACR1. a**, **b**, RBP of *Gt***ACR1 (a)** and C1C2 (b). **c**, Effects of mutations (on residues comprising the *Gt***ACR1 RBP**) on off-kinetics (top, fast closing; bottom, slow closing). Colour codes summarize the role of each residue in setting kinetics, wavelength or both. Data are mean and s.e.m; n = 10 for wild type (WT), 7 for C102A, 4 for

(absorbing light at 480 and 470 nm, respectively)^{35,36,41} making it difficult to compare to $GtACR1^{35,36}$. The GtACR1 structure reveals that most residues forming the retinal-binding pocket (RBP) are not conserved between GtACR1 and CCRs (Fig. 3a, b; Extended Data Fig. 3); in C1C2, ATR is enclosed by 16 residues (Fig. 3b), but 11 are not conserved in GtACR1 (Fig. 3a). To analyse the function of these residues, we measured absorption spectra and photocurrents in 10 mutants.

Previous studies reported that *Gt*ACR1 has five spectroscopically distinguishable intermediate states: K, L, M, N and O (with L and M as conducting states), and with opening and closing regulated by two different mechanisms (coupled fast-opening–slow-closing and slow-opening–fast-closing)^{31,33}. Confirming previous measurements, we observed that wild-type *Gt*ACR1 photocurrent peaks at $\lambda_{max} = 514$ nm with biphasic decay (τ_{off1} :54±4.5 ms; τ_{off2} :280±25ms), and that mutant *Gt*ACR1(C102A) shows decelerated τ_{off2} (32±12 s)^{31,33} (Fig. 3c, e). Notably like C102A, C102S also exhibits decelerated τ_{off1} (17±2.5 s). M105A, M105I and E163Q show markedly slowed τ_{off1} (120±30 ms, 90±3.9 ms and 110±22 ms, respectively), suggesting that Met105 and Glu163 are involved in the slow-opening–fast-closing mechanism (Fig. 3c, e).

Notably, studies of Halobacterium salinarum bacteriorhodopsin (HsBR) predict that mutation of certain residues would affect the energy barrier for the transition from K to L intermediates⁴² (closed to open in $GtACR1^{31}$). Thr198, which interacts with the β -ionone ring of ATR in C1C2, corresponds to Cys133 in GtACR1 (Fig. 3a, b). In *Hs*BR and *Cr*ChR2, mutations in residues surrounding the β -ionone affect biophysical properties; for example, M118A in HsBR changes the absorption spectrum (λ_{max} shifting from 551 to 474 nm)⁴³, and T159C in CrChR2 affects conductance and kinetics⁴⁴. However, the GtACR1(C133A) and GtACR1(C133R) mutants exhibited only slightly blue-shifted spectra, with kinetics and photocurrents comparable to wild-type levels (Fig. 3c, e; Extended Data Figs. 6-8). Thus, the RBP of the $GtACR1 \beta$ -ionone may be unusually robust (which could also depend on additional non-conserved residues around Cys133, such as Thr134 and Phe160; Fig. 3a, b; Extended Data Fig. 3). Another interesting RBP residue is Cys237, which affects key properties including absorption, kinetics and selectivity when mutated to alanine (Fig. 3c-e; Extended Data Figs. 6-8); notably, the mutant exhibits only a single fast

M105A, M105I and C133R, and 5 for the rest. *P < 0.05, **P = 0.0021, ****P < 0.0001, Kruskal–Wallis with Dunn's test. **d**, Absorption spectra of wild-type *Gt*ACR1 and the C237A mutant. Spectra were measured in one experiment. **e**, Traces of the wild-type *Gt*ACR1 and four kinetics-shifted mutants. Scale bar denoted by corresponding colour.

component of current decay ($\tau_{\rm offl}$:87 ± 4.1 ms), suggesting involvement of this residue in the slow-closing mechanism (likely along with the Cys102 residue³¹; Fig. 3c–e).

The Schiff-base region

In C1C2, two carboxylates (TM3 Glu162, TM7 Asp292) are within 4 Å of the Schiff-base nitrogen, which forms a direct hydrogen bond with Asp292 (Fig. 4a). However, in *Gt*ACR1, the TM3 residue is Ser97, and the TM7 Asp234 has a conformation quite different from Asp292 of C1C2, possibly owing to local interactions with Tyr72 and Tyr207. Notably, the overall architecture of the Schiff-base region in *Gt*ACR1 is more similar to halorhodopsins (Fig. 4a). However, in *Gt*ACR1, there is no clear electron density, suggesting water or Cl⁻ within hydrogenbonding distance of the Schiff-base forms at least a weak hydrogen bond with Asp234 (Fig. 4a). Therefore, we undertook structure-guided functional characterization of Tyr72, Tyr207 and Asp234.

First, we analysed protonation of Asp-234 using ultraviolet-visible (UV-vis) and low-temperature Fourier-transform infrared (FTIR) spectroscopy. Both assays strongly suggested the protonation of Asp234 in the dark, for the following reasons: first, wild-type and D234N mutants showed almost identical UV-vis absorption spectra (Fig. 4b; Extended Data Fig. 9a); and second, the light-induced difference-FTIR spectra at 77 K showed that a peak pair at 1,740(-)/1,732(+) cm⁻¹ in the wild type, assigned to C = O vibration of a protonated carboxylate^{39,45}, disappears in the D234N mutant (Fig. 4c; Extended Data Fig. 9b). Because the wild-type λ_{max} of the UV-vis spectra and intensity of the FTIR peak-pair remain unchanged from pH 5–9 (Extended Data Fig. 9c), Asp234 is therefore presumed to be protonated over a wide pH range, concordant with previous Raman spectroscopy³⁹.

However, surprisingly, electrophysiology revealed that D234N nearly abolishes the photocurrent (Fig. 4d). Generally, the effects of aspartate-to-asparagine mutation are small when aspartate is protonated, but in the uniquely configured *Gt*ACR1 Schiff-base environment involving close apposition of Asp234, the small difference between aspartatehydroxyl and asparagine-amino could rearrange the hydrogen-bond network around the Schiff base and thus disturb light-induced conformational changes. This concept is supported by difference FTIR spectra

Fig. 4 | The protonated Schiff base region of GtACR1 and its counterions. a, Structures of the Schiff base in GtACR1 (top), C1C2 (middle) and HsHR (bottom). Red spheres and dashed lines represent water molecules and hydrogen bonds, respectively; in GtACR1, D234 forms hydrogen bonds with the protonated Schiff base, Y72 and Y207, more similarly to HsHR than C1C2. b, Similar absorption spectra of wild-type GtACR1 and the D234N mutant, suggesting D234 protonation in the dark (see also Extended Data Fig. 9a). c, Light-induced difference FTIR spectra at 77 K. Note disappearance of the 1,740(-)/1,732(+) cm⁻ peak pair (assigned to C = O vibration of a protonated carboxylate^{39,45}) in D234N. Findings in b and c hold from at least pH 5-9 (Extended Data Fig. 9c). d, Current densities of wild-type GtACR1 and three mutants. Note D234N abolishes the photocurrent (surprising if protonated in the dark), and Y207 (but not Y72) is essential (consistent with the importance of the local hydrogen-bonded network). Data are mean and s.e.m.; n = 9 for WT, 8 for D234N, 5 for Y72F and 4 for Y207F. **P=0.01, ***P=0.0006, oneway ANOVA followed by Dunnett's test. e, Light-induced difference FTIR spectra of wild type and D234N at 170 K and 200 K. Decreased intensity of negative bands at 1,640 and 1,655 cm⁻¹ reveals smaller conformational change of transmembrane helices in D234N. All spectroscopy experiments were performed once.

in the amide-I region at 170 K and 200 K (Fig. 4e): the intensity of negative bands at 1,640 and 1,655 cm⁻¹ decreases in D234N, revealing that the conformational change of transmembrane helices in D234N is significantly smaller than in the wild type. Just as with D234N, the nearby Y207F mutation also causes loss-of-function (Fig. 4d). Considering that Phe207 naturally occurs in fully functional C1C2 and even in other natural ACRs including *Gt*ACR2 and the ZipACR variant with divergent sequences²⁷ (Extended Data Fig. 3), the precisely arranged hydrogen-bond network of the Schiff-base region thus appears essential for channel activity.

Ion conducting pathway and constrictions

To identify the ion-conduction pathway, we calculated the full electrostatic surface potential of GtACR1 compared to C1C2. C1C2 has a cation-conducting pore pathway formed by TM1, TM2, TM3 and TM7, and GtACR1 has a pore pathway at approximately the same position (Fig. 5a, b) with three marked differences. First, in a pattern opposite to that of C1C2, the surface around the pore of GtACR1 is electropositive, suitable for cation exclusion and thus anion selectivity⁴⁶ (Fig. 5a; Extended Data Fig. 10a); by contrast, C1C2 has 7 carboxylates along the ion-conducting pathway (Glu121, Glu122, Glu129, Glu136, Glu140, Glu162 and Asp292) and 14 carboxylates on intracellular/ extracellular surfaces (Fig. 5b; Extended Data Fig. 10b, d), all contributing to electronegative surfaces in and around the pore suitable for anion exclusion/cation selectivity (Fig. 5b). In GtACR1, Glu122, Glu136 and Glu162 are replaced by Ala61, Ala75 and Ser97, respectively (Fig. 5a) and Glu140 is also not conserved (Extended Data Fig. 3). Also, as shown by previous and present FTIR, residues corresponding to Glu129/Asp292 (Glu68/Asp234) are neutralized⁴⁵ (Fig. 4b, c). Finally, 12 protein-surface residues are replaced with arginine or lysine; the consistency of this pattern suggests these residues (and Arg94/Lys238) contribute to a suitable electrostatic environment for cation exclusion/anion conduction in GtACR1, confirming earlier predictions⁴⁶ (Extended Data Figs. 3, 10a, c).

Second, extracellular vestibules of GtACR1 differ markedly from C1C2. C1C2 has two extracellular vestibules (EV1 and EV2) but only EV2 is connected to the ion-conducting pathway; EV1 is occluded by hydrogen bonding among Gln95, Glu136 and Glu140 (extracellular constriction site 1, ECS1) (Fig. 5b). However, Glu136 and Glu140 are not conserved in GtACR1, and the extracellular-side TM1 and TM2 are markedly tilted, as described above (Figs. 2c, 5a; Extended Data Fig. 3). Thus, pore size becomes much larger, and EV1 becomes connected to the GtACR1 pore-pathway. Furthermore, in contrast to EV1, EV2 of GtACR1 is disconnected because of interactions among Tyr81, Arg94 and Glu223 (extracellular constriction site 2, ECS2) (Figs. 5a, 6a), indicating that EV1 serves as the primary anion-entry pathway in GtACR1. Third, the anion-conducting pathway of *Gt*ACR1 is opened not only towards the extracellular side but also intracellularly. In C1C2, although the cation-conducting pathway is opened towards the extracellular side, the cytoplasmic side is occluded by intracellular (ICS) and central (CCS) constriction sites³⁴. However, in *Gt*ACR1, residues forming the ICS in C1C2, including Tyr109, Glu122, His173 and Arg307, are replaced by Met 50, Ala61, Leu108 and Thr249, respectively, and the intracellular vestibule extends to the CCS (Figs. 5, 6b, c).

The channel is thus maintained in a closed state only by the CCS (Figs. 5, 6c). In C1C2, the CCS is formed by Ser102, Glu129 and Asn297. These three residues are conserved in *Gt*ACR1 (Gln46, Glu68 and Asn239) and its Gln46 on TM1 forms an additional hydrogen bond with Asn239, thereby further stabilizing the CCS. To test the function of these residues, we prepared 10 mutants of Gln46, Glu68 and Asn239, and measured activity by patch-clamp analysis. All Glu68 and Asn239 mutants exhibited smaller photocurrents, and Q46A showed comparable photocurrents but depolarized reversal-potential (Fig. 6d, e). Thus, all three CCS residues are important for anion-channel function, but with different roles: Glu68 and Asn239 for conductance, and Gln46 for selectivity.

Discussion

This high-resolution view into the inner workings of *Gt*ACR1 reveals that CCRs and natural ACRs share certain overall features, but also exhibit highly informative differences (especially in the architecture of the *Gt*ACR1 anion-conducting pathway, with exchange of one extracellular vestibule for another). The *Gt*ACR1 closed-state pore is also remarkable, almost entirely open with the exception of a single central constriction formed by Gln46, Asn239, Ser43 and Glu68; anions can be released intracellularly via the open conduction pore formed by Ala61, Leu108 and Thr249 (Figs. 5a, 6b). Thus, these data provide the first,

Fig. 5 | Ion-conducting pathways of *Gt*ACR1 and C1C2. a, b, Ionconducting pathways of *Gt*ACR1 (a) and C1C2 (b). The surface is coloured by the electrostatic potential calculated using PDB accession $2PQR^{51}$ for both *Gt*ACR1 and C1C2. Green, purple and orange-dashed

to our knowledge, crystal structure of any channelrhodopsin revealing an open intracellular pore pathway.

Integration of structural, electrophysiological and spectroscopic analyses uncovered unique features of the Schiff base relevant to ChR (and halorhodopsin and bacteriorhodopsin) evolution. As in HsHR, a TM7 aspartate is coordinated by two tyrosine residues in GtACR1, and the TM3 glutamate in the CCR C1C2 is instead represented in both GtACR1 and HsHR by a neutral hydrophilic residue (Fig. 4a). Furthermore, a TM2 tyrosine (Tyr72, uniformly conserved among pump-type halorhodopsins and bacteriorhodopsins) is present in GtACR1 (and is almost 100% conserved among natural ACRs; Extended Data Fig. 3)²⁷ but is dispensable for function; Y72F changes neither conductance (Fig. 4d) nor kinetics of the M-intermediate rise or decay (Extended Data Fig. 6d), characterized by fast or slow kinetics, respectively. This differs from bacteriorhodopsin, in which Y57F accelerates formation of the M-intermediate⁴⁷. Because CCRs have replaced this residue (Extended Data Fig. 3), an evolutionary model is suggested in which natural ACRs such as GtACR1 evolved from light-driven Cl pumps, and CCRs subsequently arose from natural ACRs via surface electrostatic remodelling 4,46.

Further insight into the mechanism and development of anion conduction arises from the consideration of another unusual feature of the Schiff-base region: charge distribution. In the dark, the Schiff-base nitrogen is protonated and therefore requires a mechanism to stabilize the positive charge. In *Gt*ACR1, Glu68 and Asp234 provide the only carboxylates within 6 Å of this Schiff-base nitrogen (approximately 5.4 Å and 3.5 Å, respectively), but FTIR analyses indicate that both are

circles represent the extracellular constriction site (ECS), intracellular constriction site (ICS) and central constriction site (CCS), respectively. IV, intracellular vestibule.

also protonated in the dark⁴⁵ (Fig. 4d, e). Cl⁻ does not have a chargestabilization role either, as Cl⁻ is not bound to the Schiff-base region in *Gt*ACR1³³ (Fig. 4a; unlike in *Hs*HR⁴⁸). One possible explanation is that strongly polarized water could bind to the Schiff base (behaving as a hydroxyl ion, as proposed in *Hs*BR and mutants^{2,49,50}; Supplementary Discussion), and another possibility is that the partial-negative charge of the nearby Asp234 carbonyl is sufficient to weakly stabilize the positively charged Schiff base. As a result, the net charge in the Schiff-base region may represent the achievement of perhaps the most challenging evolutionary step in the adaptation to facilitate anion conduction (alongside the acquisition of positive surface electrostatic potential throughout the pore and vestibules; Fig. 4): namely, partial local positivity despite the obligate negative nature of the Schiff base counterion.

To advance our understanding of the molecular mechanism of light-gated anion conduction, additional studies (including structural resolution of natural or designed ACRs in fully open or intermediate states) will be required. This initial high-resolution structural information provides a framework for the further development of ACR-based optogenetic tools—for example, the creation of kinetic, spectral and selectivity variants that maintain the advantages of the *Gt*ACR1 backbone including strong photocurrents, just as the initial CCR structure³⁴ allowed the development of new classes of optogenetic functionality⁴. Further insights into the evolutionary and functional relationships among different channelrhodopsin family members will continue to arise from the solution of structures that correspond to kinetic, spectral and selectivity variants, advancing basic understanding of this remarkable class of natural protein.

Acknowledgements We thank C. Lee, M. Lo, K. Geiselhart and M. Lima for technical support; K. K. Kumar, N. R. Latorraca, M. Inoue and K. Katayama for critical comments; and the APS beamline staff at 23ID-B and 23ID-D for assistance in data collection. We acknowledge support by the Stanford Bio-X and the Kwanjeong Foundation (Y.S.K.), JST PRESTO (JPMJPR1782 to H.E.K., JPMJPR15P2 to K.I.), the US Department of Energy, Scientific Discovery through Advanced Computing (SciDAC) program (R.O.D.), MEXT (17H03007 to KI., 25104009/15H02391 for HK.), J.S.T. CREST (JPM)RT1753, H.K.) and Mathers Charitable Foundation (B.K.K.). K.D. was supported by a grant for channelrhodopsin crystal structure determination from the NIMH (R01MH075957 to K.D.).

Reviewer information Nature thanks P. Scheerer, L. Tian and the other anonymous reviewer(s) for their contribution to the peer review of this work.

Author contributions Y.S.K. and H.E.K. contributed equally and either has the right to list himself first in bibliographic documents. Y.S.K. and H.E.K. expressed, purified and crystallized GtACR1, harvested crystals, and collected diffraction data. H.E.K. and K.Y. processed the diffraction data and solved the structure. Y.S.K. and L.E.F. performed electrophysiology. Y.S.K. measured UV-vis spectra. S.I. performed FTIR experiments under the guidance of K.I. and H.K. J.M.P. and R.O.D. provided input on structural considerations. C.R. and K.E.E. performed cell cultures and molecular cloning for electrophysiology. K.D. initiated and supervised this ChR structure/function project; Y.S.K., H.E.K., B.K.K. and K.D. planned and guided the work, and interpreted the data. Y.S.K., H.E.K. and K.D. prepared the manuscript and wrote the paper with input from all the authors.

Competing interests The authors declare no competing interests.

METHODS

Sample sizes were determined based on previous literature and best practices in the field; no statistical methods were used to predetermine sample size. No experiments in animals were conducted in this paper and hence experiments were not randomized or blinded.

Cloning, protein expression and purification. The crystallization construct of GtACR1 was generated with several features to enhance protein purification and crystallogenesis. The flexible 13 amino acids at the C terminus were truncated after Gly282. A Flag tag followed by the 3C protease cleavage site was added to the N terminus and an enhanced GFP (eGFP) with a His10 tag and the 3C site was attached to the truncated C terminus via the 3C cleavage site. The finalized GtACR1 crystallization construct was expressed in Sf9 cells using the BestBac (Expression Systems) baculovirus system. Cell cultures were grown to a density of 4×10^6 cells ml⁻¹, infected with *Gt*ACR1 baculovirus, and shaken at 27 °C for 18 h. Then, 20 µM all-trans retinal (ATR) (Sigma) was supplemented to the culture and incubation continued for 42 more hours, and cell pellets were collected and stored at -80 °C. To purify GtACR1, the pellets were lysed with a hypotonic lysis buffer (20 mM HEPES pH 7.5, 1 mM EDTA and protease inhibitors). The cell debris was then homogenized with a glass douncer in a solubilization buffer (1% *n*-dodecyl-β-D-maltopyranoside (DDM), 0.06% cholesteryl hemisuccinate tris salt (CHS), 20 mM HEPES pH 7.5, 500 mM NaCl, 20% glycerol, 10 mM imidazole and protease inhibitors) and solubilized for 2 h in 4 °C. The insoluble cell debris was removed by centrifugation (38,000g, 25 min), and the supernatant was mixed with the Ni-NTA agarose resin (Qiagen) for 2 h in 4 °C. The Ni-NTA resin was collected into a glass chromatography column, washed with 20 column volumes of a wash buffer (0.05% DDM, 0.01% CHS, 20 mM HEPES pH 7.5, 500 mM NaCl, 20% glycerol and 20 mM imidazole) and was eluted in a wash buffer supplemented with 250 mM imidazole. The Ni-NTA eluent was then supplemented with 2 mM CaCl₂ and was loaded over anti-Flag M1 resin over 1 h. The protein was then washed with a Flag wash buffer (0.05% DDM, 0.01% CHS, 20 mM HEPES pH 7.5, 300 mM NaCl, 5% glycerol and 2 mM CaCl₂) and eluted with a Flag elution buffer (0.05% DDM, 0.01% CHS, 20 mM HEPES pH 7.5, 300 mM NaCl, 5% glycerol, 0.2 mg ml⁻¹ Flag peptide and 3 mM EDTA). After the cleavage of the Flag tag and eGFP-His10 by His-tagged 3C protease, the sample was reloaded onto the Ni-NTA column to capture the cleaved eGFP-His₁₀. The flow-through containing GtACR1 was collected, concentrated and purified through gel-filtration chromatography in a final buffer (100 mM NaCl, 20 mM HEPES pH 7.5, 0.05% DDM and 0.01% CHS). Peak fractions were pooled and concentrated to 30 mg ml⁻¹ (Extended Data Fig. 1b). Crystallization. Purified GtACR1 protein was crystallized using the lipidic cubic phase (LCP) method as described previously³⁴. Protein was mixed with monopalmitolein (Nu-chek) at a weight ratio of 1:1 (protein:lipid) using a coupled syringe mixing device. Then, 20-25 nl protein-LCP mixture drops were accurately dispensed on a 96-well sandwich plate and overlaid by 500 nl of precipitant solution by the Gryphon LCP robot (Art Robbins Instruments). Initial crystals were obtained in 10% (w/v) polypropylene glycol P 400 (PPG P400), 100 mM MES pH 6.0 and 100 mM potassium formate; the best crystals were obtained in 10-12% (w/v) polypropylene glycol P 400 (PPG P400), 100 mM MES pH 6.0, 100 mM potassium formate and 1-3% 1-butanol. Crystals were harvested using micromeshes (MiTeGen), and were flash-cooled in liquid nitrogen without any additional cryoprotection. Data collection and structure determination. X-ray diffraction data were collected at Advanced Photon Source GM/CA-CAT beamline 23ID-B and 23ID-D using a micro beam size of $10 \times 10 \,\mu\text{m}^2$, at a wavelength of 1.033 Å. Small wedge data, each consisting of 5-20°, were collected from single crystals, and 131 collected datasets were processed automatically using KAMO⁵². Each dataset was indexed and integrated using XDS⁵³, and classified using the correlation coefficients between data sets. Eighty datasets in the best cluster were scaled and merged using XSCALE. The structure was determined by molecular replacement with the program MoRDa (Vagin and Lebedev; http://www.biomexsolutions.co.uk/ morda), using the cation channelrhodopsin C1C2 (PDB accession 3UG9) and G11A mutant of SARS-CoV 3C-like protease (PDB accession 2PWX) as the search models. However, the 2PWX model was not fitted to electron density at all and removed. The resultant structure was iteratively refined using Refmac554, Phenix55 and MR-rosetta⁵⁶, and manually rebuilt in Coot⁵⁷. The final model contained 95.7, 4.1 and 0.3% in the favoured, allowed and outlier regions of the Ramachandran plot, respectively. Final refinement statistics are summarized in Extended Data Fig. 1. All molecular graphics figures were prepared with Cuemol (Ishitani; http:// www.cuemol.org).

Electrophysiology. HEK293 cells (Thermo Fisher, authenticated by the vendor, not tested for mycoplasma contamination) were plated on poly-D-lysine coated glass coverslips (Fisher) at 10% confluency, and were transfected with 0.5 µg of a plasmid and 1 µl lipofectamine 2000 (Thermofisher Scientific) per well. After 24-48 h of transfection, cells were placed in an extracellular tyrode medium (150 mM NaCl, 4 mM KCl, 2 mM CaCl₂, 2 mM MgCl₂, 10 mM HEPES pH 7.4 and 10 mM glucose). A borosilicate patch pipette (Harvard Apparatus) with resistance of 3–6 M Ω was filled with intracellular medium (140 mM potassium-gluconate, 10 mM EGTA, 2 mM MgCl₂ and 10 mM HEPES pH 7.2). The photocurrent and kinetic measurements were performed in voltage-clamp mode at membrane potential of -70 mVand -10 mV, respectively. Light was delivered with the Spectra X Light engine (Lumencor) connected to the fluorescence port of a Leica DM LFSA microscope, and a 513/15 filter was used for green light generation. To determine channel kinetics and photocurrent amplitudes, traces were first smoothed using a lowpass Gaussian filter with a -3 dB cutoff for signal attenuation and noise reduction at 1,000 Hz and then analysed in Clampfit software (Axon Instruments). Liquid junction potentials were corrected using the Clampex built-in liquid junction potential calculator as previously described²². Current density was calculated by dividing peak photocurrent amplitude by cell's membrane capacitance, which was calculated from the Clampex built-in membrane test. Statistical analysis was performed with t-test or one-way ANOVA, and the Kruskal-Wallis test for non-parametric data, using Prism 7 (GraphPad) software.

Light-induced difference FTIR spectroscopy. Wild-type and D234N mutant GtACR1 were reconstituted into a mixture of POPE and POPG (molar ratio = 3:1) with a protein-to-lipid molar ratio of 1:30 by removing DDM with Bio-Beads (SM-2, Bio-Rad). The reconstituted samples were washed three times with buffers at pH 5.0 (2 mM citrate-NaOH), pH 7.0 (2 mM HEPES-NaOH) or pH 9.0 (2 mM borate-NaOH) with 1 mM NaCl. The pellet was re-suspended in the same buffer, with the concentration adjusted to 1.7 mg ml⁻¹. A 60 μ l aliquot was placed onto a BaF2 window and air-dried. FTIR spectroscopy was applied to the films hydrated with 1 µl H₂O at 77 K, 170 K and 200 K as described previously⁵⁸. In brief, the sample was placed in an Oxford DN-1704 cryostat mounted in the Bio-Rad FTS-40 spectrometer (instrumental resolution of FTIR is 2 cm⁻¹). For the formation of photo-intermediates at 77 K, samples were illuminated at 500 nm (interference filter) from a 1-kW halogen-tungsten lamp for 2 min and photo-reversed with >600 nm light (R-62 cut-off filter, Toshiba) for 1 min. For formation of photointermediates at 170 K and 200 K, samples were illuminated with >500 nm light (Y-52 cut-off filter, Toshiba) for 1 min. For each measurement of FTIR spectroscopy, 256 interferograms were accumulated; 40 identical recordings at 77 K and 7 identical recordings at 170 K and 200 K were averaged.

Measurement of UV absorption spectra. Protein absorbance spectra were measured with an Infinite M1000 microplate reader (Tecan Systems Inc.) using 96 well plates (Thermofisher scientific). The GtACR1 samples were suspended in a buffer containing 100 mM NaCl, 0.05% DDM, 0.01% CHS, and 20 mM sodium citrate, sodium acetate, sodium cacodylate, HEPES, Tris, CAPSO or CAPS. pH was adjusted from 4 to 10 by the addition of NaOH or HCl. Recorded spectra value was averaged from 20 measurements from a single session.

Reporting summary. Further information on research design is available in the Nature Research Reporting Summary linked to this paper.

Data availability. The protein coordinate and atomic structure factor have been deposited in the Protein Data Bank (PDB) under accession number 6CSM. The raw diffraction images have been deposited in the SBGrid Data Bank repository (ID: 569). All other data are available from the corresponding authors upon reasonable request.

Extended Data Fig. 3 | Structure-based sequence alignment of microbial opsin genes. The sequences are *Gt*ACR1 (GenBank accession AKN63094.1), *Gt*ACR2 (GenBank AKN63095.1), *Zip*ACR (GenBank APZ76709.1), *Psu*ACR1 (GenBank ID: KF992074.1), the chimaeric channelrhodopsin between *Cr*ChR1 and *Cr*ChR2 (C1C2, PDB code 3UG9)³⁴, *Cr*ChR1 (GenBank 15811379), *Cr*ChR2 (GenBank 158280944), ChR1 from *Volvox carteri* (*Vc*ChR1, UniProtKB B4Y103), ChR1 from *V. carteri* (*Vc*ChR2, UniProtKB ID: B4Y105), Chrimson (GenBank ID: AHH02126.1), ChR from *Tetraselmis striata* (*Ts*ChR, GenBank ID:

KF992089.1), *Hs*BR (PDB code 1C3W)⁵⁹, *Hs*HR (PDB code 1E12)⁴⁸, and *Krokinobacter eikastus* rhodopsin 2 (KR2, PDB code 3X3B)⁶⁰. The sequence alignment was created using PROMALS3D⁶¹ and ESPript 3⁶² servers. Secondary structure elements for *Gt*ACR1 are shown as coils and arrows. 'TT' represents turns. Cysteine residues forming intermolecular and intramolecular disulfide bridges are highlighted in green and yellow, respectively. The residues of retinal-binding pockets are coloured pink. The residues in the Schiff base region are coloured cyan. The residues forming the ECS2 and CCS are coloured orange and blue, respectively.

Supplementary Discussion

Water molecules around the Schiff base region

In the *Gt*ACR1 structure, several $2F_o - F_c$ and $F_o - F_c$ electron densities of putative water molecules were detected near the Schiff base. Since the densities are not identical among chains A-D and the resolution of present structure is moderate (2.9 Å), we modeled just 4 water molecules in the final structure. 2 water molecules coordinated by Asp-234 and Tyr-72, were detected in chains B and C. Another 2 water molecules coordinated by Arg-94, were detected in chains A and B (EDFig. 2c). Their electron densities and B-factors are very reasonable for wellordered water molecules (B-factors: 54.87, 52.64, 50.28, and 59.19, respectively). However, there remain unassigned densities in chains A and B (EDFig. 2c). Especially in chain B, there is relatively strong positive $F_o - F_c$ electron density between the Schiff base nitrogen (Asp-234) and Trp-98, and it is possible that weakly coordinated water or hydroxyl ion binds near the Schiff base. Further studies, including the determination of higher-resolution structure and additional spectroscopic analysis, will be needed to more fully reveal water distribution in the Schiff base region.
