\*This paper evolved from the authors' participation in a National Academy of Sciences (NAS) panel review of regulation in the railroad industry, *Modernizing Freight Rail Regulation* (2015), National Academies Press, Washington, DC. The other panel members—Dick Schmalensee, Ken Boyer, Jerry Ellig, José A. Gómez-Ibáñez, Anne Goodchild, and Thomas Menzies—provided a number of invaluable feedback throughout the process of completing this paper. Earlier versions have been presented to the Association of Transport, Trade, and Service Studies, Railroad-Shipper Transportation Advisory Council, the Advanced Workshop in Regulation and Competition, and the Transportation and Public Utilities Group at the 2019 ASSA meetings. The authors gratefully acknowledge comments and discussions that emanated from these audiences. We would also like to thank Ray Atkins, Jerry Ellig, William Huneke, Patrick McCarthy, Keaton Miller, Tom Menzies, Russell Pittman, David Sappington, Dick Schmalensee, and Clifford Winston for detailed comments on a previous draft. We thank Kevin Henrickson for research assistance.

## **Abstract**

A number of formerly regulated multiproduct industries have a transitional or permanent residual regulatory mandate to protect consumers from “excessive” prices. The legislation that deregulated most rail rates contains such a provision. Fulfilling this mandate has been challenging because of the cost and administrative burden to shippers in obtaining regulatory relief. This paper analyzes a benchmark price approach to identify “excessive” prices in multiproduct industries subject to residual price regulation. The empirical analysis demonstrates that our mechanism has the potential to fulfill this statutory mandate at lower cost, with less administrative burden, and without significant adverse financial consequences for the railroads.

Keywords: Railroads, Network Industries, Monopoly, Rate Reasonableness

## 1. Introduction

A number of formerly regulated multiproduct industries have a transitional or permanent residual regulatory mandate to protect consumers from “excessive” prices. The Federal Energy Regulatory Commission (FERC) is required to ensure that all wholesale electricity prices are “just and and reasonable” and “not unduly discriminatory or preferential,” even in parts of the United States with formal bid-based short-term markets for wholesale electricity. FERC has a similar regulatory mandate for natural gas and oil transportation despite the fact that prices for most natural gas and oil movements are set through bilateral negotiations between the pipeline owner and the purchaser of wholesale natural gas or oil. In the aftermath of the Airline Deregulation Act of 1978, the Civil Aeronautics Board (CAB) had a transitional mandate to ensure that airfares were not “unjust and unreasonable.” The Staggers Act of 1980, which partially deregulated the railroad industry, imposes a regulatory mandate on the Surface Transportation Board (STB), the industry regulator that replaced the Interstate Commerce Commission (ICC), to protect captive shippers from “excessive” prices.

These regulatory mandates have proven challenging to enforce to the satisfaction of the parties involved because of the conceptual difficulty in defining a “just and reasonable” price for a multiproduct firm with substantial economies to scope in production. Darius Gaskins, the former CEO of Burlington Northern railroad, argues that this residual regulatory challenge in the railroad industry “still has not been solved to everyone’s satisfaction after 150 years of effort.” (Gaskins (2008), p. 1). That is because a railroad provides thousands of products, depending on the commodity and distance shipped, and both the incremental cost of a shipment and marginal cost of including an additional ton in the shipment exclude the vast majority of the railroad’s total cost of production.<sup>1</sup> This implies that setting each shipment price equal to either the average incremental cost of the shipment or the marginal cost of shipping an additional ton of that product would not provide sufficient revenue for the railroad to cover its annual costs. The railroad must charge prices above the average incremental cost and the marginal cost of shipping an additional ton for a substantial fraction, if not all, of its shipments in order to recover its total cost of production.

The STB enforces the prohibition against “excessive” prices in the Staggers Act through an administrative process that must first establish that the railroad is “dominant” in the provision of the shipment. The STB must then determine if the tariff charged by the dominant railroad is “excessive.” This administrative process involves presenting evidence to the STB supporting the “excessive” price claim which requires significant time and legal expense for the shipper seeking rate relief. These time and monetary costs have limited the number

---

<sup>1</sup>Costs not caused by a shipment or moving an additional ton in a shipment include the cost of the track, rolling stock, management salaries and benefits, and the vast majority of labor costs.

rate relief cases filed, particularly by small shippers. In the 23 years that the STB has been in existence there have been only 51 cases filed with only 12 resulting in an unreasonable rate finding.<sup>2</sup> These features of the rate relief process have increasingly led to calls for its reform.

A major challenge to meaningful reform is that traditional cost-based approaches to price regulation are not available for a multiproduct firm with pricing flexibility for a significant fraction of the products it sells.<sup>3</sup> The large number of products sold by railroads and the large share of common costs in the railroad’s total cost of production imply that even if the railroad’s multiproduct cost function was known with certainty, this would not make the job of setting the threshold for an “excessive” price for a shipment any easier. The STB would be able to compute the average incremental cost of a shipment or the marginal cost of shipping an additional ton with certainty, but this would only change the STB’s problem from one of determining the value of an excessive price for the shipment to determining the value of an excessive markup over the average incremental cost or marginal cost of the shipment.

The Ramsey-pricing solution of setting the percent markup over marginal cost for each shipment proportional to the inverse of the elasticity of the demand for the shipment flies in the face of the Staggers Act mandate to protect captive shippers. By definition, captive shippers have no other economically viable alternative but the railroad for their shipment and for that reason have a small elasticity of demand for the shipment and would therefore be charged a price that reflects an extremely high markup over the marginal cost of the shipment. This logic rules out Ramsey-pricing as a solution, because it places a significant burden for common cost recovery on captive shippers.<sup>4</sup>

Further complicating the process of crafting an alternative rate relief process is the fact that there are unlikely to be significant short-run total welfare losses associated with railroads charging shippers “excessive” prices. Profit-maximizing railroads should not charge shippers prices that are so high that a movement with an economic benefit to the shipper greater than the incremental cost to the railroad of providing it will not occur. In this case, setting

---

<sup>2</sup>Of the remaining 39 cases, 2 were withdrawn, 26 resulted in a settlement between the railroad and shipper, and 11 ultimately found the tariff rate charged to be reasonable.

<sup>3</sup>The regulator can only set the prices of products where the firm does not have pricing flexibility, which still leaves open the question of what fraction of common costs the firm is entitled to recover from these products.

<sup>4</sup>It is important to emphasize that for the case of zero cross-price elasticities of the demands for the products sold by a multiproduct firm, Ramsey pricing implies setting the largest percent markups of price ( $p_i$ ) over marginal cost ( $c_i$ ) for products with the smallest (in absolute value) own-price elasticity of demand ( $\epsilon_i$ ). Specifically, the markup for product  $i$ ,  $M_i = \frac{p_i - c_i}{p_i} = -\frac{k}{\epsilon_i}$  for some  $0 < k < 1$ . Therefore, relative markups,  $\frac{M_i}{M_j}$  (the ratio of the percent markup of product  $i$  relative to the percent markup of product  $j$ ), under Ramsey-pricing are the same as those under monopoly pricing by a multiproduct firm. Ramsey-pricing increases product-level percent markups to recover the multiproduct firm’s total cost of production, whereas the multiproduct monopolist raises them to the point that maximizes the firm’s profits.

a shipment price high enough to curtail the shipment would reduce the total contribution to the railroad’s fixed and common cost recovery. Nevertheless, the railroad is likely to charge a captive shipper a rate that transfers virtually all of the economic surplus associated with the movement to the railroad. This logic can even be used to argue that there would be little, if any, long-run total welfare loss for a railroad that is the only supplier for a movement. This railroad can be expected to factor in the impact of its pricing decision today on the financial viability of the shipper and the discounted present value of the economic rents the railroad is able to extract from the shipper in the future.

Although it is possible to make a long-run economic efficiency argument in favor of protecting captive shippers, in the short-run, “equity” concerns appear to be the primary rationale for this regulatory mandate.<sup>5</sup> Specifically, what is highest rate that the railroad can charge for a shipment and still provide the shipper with a “fair” share of the economic surplus associated with the movement. An “excessive” or “unreasonable” price implies that the shipper is capturing more than its “fair” share of the economic surplus associated with the shipment.

This paper analyzes an alternative approach to determining if the price charged by a multiproduct firm is “unreasonable” that does not require knowledge of the multiproduct firm’s cost function or the elasticity of demand of individual products. This methodology relies on a set of circumstances that is increasingly prevalent in many formerly regulated industries, the existence of a large sample of “reasonable prices” for products along with the observable characteristics of each of these products. We use this sample to estimate nonparametrically the conditional distribution of “reasonable” prices given product characteristics and then use this conditional distribution to construct a benchmark price based on the observable characteristics of a shipment suspected of having an “excessive” or “unreasonable” price. If the actual price exceeds this benchmark price, then the price of the shipment could be deemed worthy of further regulatory scrutiny because of this evidence that the shipper is not receiving its “fair” share of the economic surplus associated with the shipment.

There are two important considerations in setting the value of a benchmark price for a shipment. First is the probability of false positives—reasonable prices that are incorrectly found to exceed the benchmark. Second is the possibility of false negatives—unreasonable prices that are incorrectly found not to exceed the benchmark price. We investigate this issue with a Monte Carlo study where we first estimate the conditional distribution of reasonable prices given shipment characteristics on data simulated from markets where the firm

---

<sup>5</sup>Shipments where the railroad faces limited competition from other transportation services suppliers, none of the competitors would have an incentive to take full account of the impact of today’s pricing decision on the future financial viability of the shipper.

faces a reasonable level of competition and then apply our benchmark price methodology using this estimated distribution with data simulated from a mixture of “reasonable” and “unreasonable” shipment prices.

Similar to the case of statistical hypothesis testing, a rule for setting the benchmark price that minimizes the sum of squares of misclassification errors argues in favor of an approach that requires overwhelming statistical evidence against a price being reasonable before it is deemed “excessive.” Our Monte Carlo results finds that setting the value of the benchmark price between the upper 5 percent and upper 1 percent of the conditional distribution of “reasonable” prices given the shipment characteristics minimizes the sum of squared misclassification errors for a range of distributions of unreasonable shipment prices.

Another important consideration in the design of our approach is the revenue impacts of resetting shipment prices that violate the benchmark price to a mitigated value at or below the benchmark price. If violations of the benchmark occur too frequently and if the mitigated shipment price is set too low, there is a risk that this may cause a railroad that is revenue adequate—it is earning sufficient revenues to recover its total cost of production—to become revenue inadequate. Using the choice of the benchmark price recommended by our Monte Carlo analysis, we explore the impact of different choices for the mitigated or “reasonable” shipment price in the event that an actual price violates our benchmark price using actual data from the STB’s Waybill sample for four broad classes of shipments: (1) petroleum products, (2) farm products, (3) coal, and (4) chemical products.

In all cases, we find that for our choice of the benchmark price, re-setting the price charged equal to any of our three choices for a “reasonable” price for the shipment has a very small percentage impact of the railroad’s aggregate revenue.<sup>6</sup> However, for all of our choices of the “reasonable” price, we find that the average value of the difference in prices between the actual “unreasonable” price and the “reasonable” price is a substantial percentage of the average value of the “unreasonable” price, which is consistent with our procedure providing significant rate relief to a shipper facing prices that our procedure deems are “unreasonable.”

The remainder of paper first summarizes the pre- and post-Staggers Act of 1980 regulatory framework governing the railroad industry. This section summarizes the shortcomings of the current approach to regulating “unreasonable” prices charged to captive shippers and why we believe our benchmark pricing approach helps to overcome these shortcomings. Section III outlines our approach to estimating the conditional distribution of reasonable prices given shipment characteristics. Section IV presents the Monte Carlo study we use

---

<sup>6</sup>A less conservative approach to setting the value of the benchmark price, at for example the conditional median price for the observed shipment characteristics, will lead to more prices being deemed “excessive” and larger revenue losses from re-setting the actual price to this benchmark price level.

to compare methodologies for computing the value of the benchmark price from the conditional distribution of reasonable prices given product and shipment characteristics. Section V reports on the results of applying our methodology to the STB’s Waybill sample for four broad classes of shipments to assess the extent of rate relief obtained by the shipper and the impact of this rate relief on annual railroad revenues for different approaches to determining an “unreasonable” shipment price. Section VI discusses possible uses for our benchmark pricing mechanism in carrying out the STB’s statutory mandate to protect captive shippers from excessive prices. Section VII summarizes our results and proposes directions for future research.

## **II. A Brief History of Railroad Regulation**

The history of regulatory oversight of the railroad industry since the inception of the Interstate Commerce Commission (ICC) in 1887 can be divided into the pre-Staggers Act period when prices and entry into and exit from railroad sector were regulated by the ICC, and the post-Staggers Act period when railroad price regulation and entry and exit regulation were largely eliminated. Residual regulation of these functions was conducted by ICC until 1995, when it was eliminated by the ICC Sunset Act. This act also created the Surface Transportation Board (STB) which currently carries out these functions. For both the pre- and post-Staggers regimes we highlight the regulatory challenges facing the railroad industry. This section concludes with a discussion of why we believe the use of our price benchmark approach for “excessive” rate regulation could reduce the cost and improve the effectiveness of the STB’s current approach to residual price regulation.

### ***II.1. Pre-Staggers Act Railroad Regulation***

Prior to the passage of the Staggers Act, rates for all railroad shipments were subject to approval by the ICC.<sup>7</sup> Rate proposals were typically provided by rate bureaus composed of railroad staff that operated cooperatively with antitrust immunity. The ICC would then review these rate proposals and frequently prohibited their implementation or significantly reduced them before they were allowed to be implemented. As Stone (1991) notes, rate reductions to respond to competition from other modes of transportation were often blocked.

This regulatory structure did not encourage efficient operation of the rail network or maximize the revenues earned by the railroads. By the late 1970s, the railroad industry was on the brink of financial collapse, and many individual railroads were bankrupt. It was widely held that the regulatory structure that existed at the time impeded the ability of railroads to meet new forms of competition and impeded innovation in the industry.<sup>8</sup>

---

<sup>7</sup>There is a voluminous literature on railroad regulatory policy. Keeler (1983) provides a comprehensive survey.

<sup>8</sup>See, for example, Keeler (1983), Gallamore and Meyer (2014) and others cited therein for the factors leading to regulatory reform.

The Railroad Revitalization and Regulatory Reform Act of 1976 (4R Act) and the Staggers Rail Act of 1980 provided for significantly reduced federal regulatory oversight of the railroads. This legislation introduced new mechanisms governing the regulation of rates, allowed confidential contracts between railroads and shippers at negotiated rates, and eased impediments to rail line abandonment and to mergers.

## ***II.2. Post-Staggers Act Railroad Regulation***

The 4-R Act and Staggers Act placed a greater emphasis on market forces to discipline rates. The effects of these legislative changes on the railroad industry have been dramatic, with substantial decreases in costs, rates, and the size of the rail network as well as a tremendous consolidation of firms.<sup>9</sup>

The legislation anticipated the need to protect shippers that do not have an economically viable alternative for a shipment. It established the notion of "market dominance" to protect these so-called captive shippers from "excessive" rates. The STB has the jurisdiction to consider the reasonableness of a rate only if there is a finding that the railroad is "market dominant" over the movement.

Market dominance is defined as the absence of effective competition from other railroads or modes of transportation (49 USC §10707). A rate for shipment is automatically considered reasonable if the revenue the railroad receives ( $R$ ) for it does not exceed 180 percent of the railroad's "variable cost," ( $VC$ ) as determined by the STB's costing methodology (49 USC §10707(d)(1)(A)).<sup>10</sup> If a disputed rate fails the  $R/VC \leq 180$  percent test and is found to be serving a market lacking effective competition so that the railroad is "market dominant," the STB can rule on whether the rate is reasonable.<sup>11</sup> If STB subsequently finds the rate to be unreasonable, it must order the railroad to compensate the shipper for overpayments, and it may prescribe the maximum rate the railroad can charge for future movements (49 USC §11704(b), §10704(a)(1).)

Until recently, rate reasonableness cases had to be initiated by the shipper.<sup>12</sup> That is, rates would be set and the regulatory process would begin with a challenge by a shipper after the rate was set. An aggrieved shipper must have a rate greater than 180 percent of the

---

<sup>9</sup>These changes are documented in McFarland (1989), Barnekov and Kriet (1990), Berndt et al. (1993), Velturo et al. (1992), Burton (1993), Wilson (1994; 1997), MacDonald and Cavalluzzo (1996), Grimm and Winston (2000), Ellig (2002), Bitzan and Keeler (2003), Bitzan and Wilson (2007), Winston et al. (2010), Schmalensee and Wilson (2016).

<sup>10</sup>We put "variable costs" in quotes to denote the fact that this is primarily a regulatory construct that is inconsistent with the economic theory of multiproduct cost functions for the reasons noted in Wilson and Wolak (2016).

<sup>11</sup>See Eaton and Center (1986) and Wilson (1996) for more details on process used to determine market dominance.

<sup>12</sup>The Surface Transportation Board Reauthorization Act of 2015 now authorizes the Board to investigate on its own initiative (S.808, Section 11).

URCS “variable costs” for the shipment and the regulatory authority must find the railroad is “market dominant” before the reasonableness of the rate can be considered.

Shippers historically brought “excessive” rate cases under the Stand-Alone Cost (SAC) criteria introduced by the ICC in 1985 (Coal Rate Guidelines, Nationwide. 1985 [1 ICC.2d 520, 1985 WL 56819 (ICC)]).<sup>13</sup> In a SAC case, the stand-alone cost of a hypothetical railroad providing the shipment is used to establish an upper bound on the rate that is deemed reasonable for the shipment. The time and effort required to make a SAC claim against a railroad are substantial. The process of determining the SAC for a hypothetical railroad providing the shipment is extremely complex with ample room for disagreement between parties about the many assumptions underlying the calculation. Each of these points of disagreement must be litigated at the STB, which makes the entire process both expensive and time-consuming. The STB estimates the costs of pursuing a SAC case can exceed \$5 million.<sup>14</sup>

Cost and complexity of SAC rate cases have led to a number of legislative and policy changes by the STB to reduce the time and cost of filing for rate relief. In the ICC Termination Act of 1995, Congress ordered the STB to develop expedited procedures for resolving disputes. In response, the STB introduced the Three-Benchmarks standard in 1996. In 2006, the STB revised the Three-Benchmarks rules and introduced the Simplified-SAC rules. Both of these expedited procedure limit the evidence that parties can submit and sets a time limit for decisions.<sup>15</sup> These simplified procedures also limit the amount of refunds a shipper can obtain from “excessive” prices.

To implement the first stage of the excessive rate test, the “variable cost” of the shipment under consideration must be calculated, and the legislation mandates that the STB have a costing methodology.<sup>16</sup> The ICC had used Rail Form A, an accounting-based cost allocation system for railroad services and activities, since 1939. Under the Staggers Act regulatory reforms, the ICC was charged with developing an updated method to determine “economically accurate railroad costs directly and indirectly associated with particular movements of

---

<sup>13</sup>In the Coal Rate Guidelines, the Commission adopted the principle of “Constrained Market Pricing” wherein a captive shipper should not be required to pay more than necessary for the rail carrier to earn adequate revenue for the service provided or for any productive inefficiencies in how the rail carrier provides the service. Hence, early “excessive” rate cases could be brought under three different standards: (1) the SAC test, (2) excessive profits earned by a railroad that was revenue adequate, and (3) management inefficiencies included in the rate charged. However, all cases were brought under SAC until the simplified guidelines for bringing rate cases were introduced in 1996.

<sup>14</sup>STB Ex Parte No. 715, Rate Regulation Reforms, July 8, 2013, pp. 10–11.

<sup>15</sup>See Pittman (2010) and Wilson and Wolak (2016) for more complete discussions of these procedures.

<sup>16</sup> The Staggers Rail Act, §10705a(m)(1), required ICC to determine variable costs by using its Rail Form A costing method or to adopt an alternative method.

goods, including the variable costs associated with particular movements.”<sup>17</sup> To comply, the ICC developed the Uniform Railroad Costing System (URCS), which was adopted in 1989, and shares a methodological approach with earlier allocated cost accounting schemes.

Wilson and Wolak (2016) examine theoretical and empirical validity of URCS methodology for computing the “variable cost” of a shipment. They argue that it is an *ad hoc* cost allocation methodology that is inconsistent with the economic theory of multiproduct costing. Using shipment prices from the STB’s Waybill sample, the authors found many instances of railroads providing a shipment at a price that is less than the URCS “variable cost.” This “irrational” behavior by railroads implied by the URCS costing methodology and its inconsistency with the economic theory of multiproduct costing argues against the use of the URCS “variable cost” in determining excessive rates. Wilson and Wolak (2016) conclude that URCS costs do not meet the law’s requirement for economically accurate shipments costs, and therefore have little relevance to the price charged for a given unit of traffic, contrary to their use in the law’s  $R/VC$  formula. The STB’s own Railroad–Shipper Transportation Advisory Council recently referred to URCS as “an outdated and inadequate costing system.”<sup>18</sup>

Despite the fact that this costing system can deny rate relief to worthy shippers and shipments, it is mandated by legislation. In addition to being used in screening traffic for rate relief eligibility according to the  $R/VC$  formula, URCS is used in subsequent procedures to determine market dominance, to make assessments of whether a challenged rate is reasonable, and, if necessary, to prescribe the maximum tariff rate a railroad may charge. URCS is also used to measure avoidable costs when a railroad applies to abandon a line and in calculating compensation fees for mandated access (STB 2010, 6–8).<sup>19</sup> It is also used by others to judge levels of market power and trends in the industry.<sup>20</sup>

Even if the STB had access to perfect measures of the incremental cost for all possible shipments a railroad could provide, this information would not get it any closer to determining what is an “excessive” price or what a “reasonable” price is for a shipment because

---

<sup>17</sup>Cost accounting principles in Title III, Section 301, §11162 of the Staggers Rail Act of 1980.

<sup>18</sup><http://www.stb.dot.gov/stb/docs/RSTAC/RSTAC-%20URCS-%20White-%20Paper-%20on-%20URCS-%20November-%202022.pdf>.

<sup>19</sup>Mandated access is when one railroad is required to sell access to some or all of its rail network to another railroad.

<sup>20</sup>For example, in 2006 the U.S. Government Accountability Office (GAO) examined trends in shipments having rates with various  $R/VC$  percentages to determine whether railroads were obtaining and exercising more market power over time (GAO 2006). In finding that the share of traffic having  $R/VC$ s above 180 percent had dropped from 1985 to 2004, GAO surmised that the market power of railroads had been declining. Coincidental with these findings, however, GAO found that the amount of traffic having  $R/VC$ s exceeding 300 percent had increased from 4 to 6 percent, which caused the agency to question whether railroads were in fact becoming more effective in exploiting market power when they possessed it (GAO 2006, 43).

of the substantial fixed and common costs associated with providing rail service. Financial viability of a railroad requires it to charge prices in excess of the incremental and marginal cost of a shipment for a significant fraction or all shipments in order to recover these fixed and common costs. With perfect estimates of the incremental and marginal cost of a shipment, the STB would face the equally challenging tasks of determining what shipment price is an “excessive” markup over the average incremental cost or marginal cost of a shipment and what shipment price is a “reasonable” markup over these shipment cost measures.

Our price benchmark approach explicitly addresses these challenges by using information from shipments that the STB has determined are reasonably priced to determine what is an “excessive” price for a shipment and what is a “reasonable” price for a shipment. Our price benchmark approach should also be significantly less costly for shippers both in terms of time and legal expense. It also does not involve the use of the URCS costing methodology. It would also make use of the fact that an increasing number of shipments are occurring at negotiated rates where the STB has determined that the railroad faces effective competition for the shipment.

Prices for shipments that the STB has determined are reasonably priced are used estimate the conditional distribution of shipment prices given observable characteristics of the shipment that account for differences in shipment costs, the commodity shipped and other observable characteristics of the shipment. We then use this estimated conditional distribution to compute a price benchmark for a potentially “unreasonably” priced shipment based on its observable characteristics. A percentile of the reasonable price conditional distribution is the benchmark relative to which the actual rate is compared to identify unreasonable prices. This approach can be applied to all markets, railroads, and commodities utilizing data that are easily obtained and/or collected by the STB, primarily through its Waybill sample.

We do not claim that our benchmark price distribution estimation procedure recovers the conditional distribution of “competitive” prices given shipment characteristics, only that it recovers the conditional distribution of prices for the set of shipments that the STB has determined are “reasonably” priced. Our empirical application using the Waybill data assumes a specific criteria for a shipment to enter our estimation sample, but there nothing in our approach that prevents the STB from using a different criteria to select this estimation sample.<sup>21</sup>

The maintained assumption behind our approach is that the conditional distribution of

---

<sup>21</sup>We also recognize that railroads may take into account which shipments are used to construct our benchmark price distribution in how they price these shipments. However, the increasing number of shipments that are exempt from STB maximum price regulation and the methodology we use to compute the benchmark price described in Section IV argues against this being a significant shortcoming of our approach.

prices given a broad class of product and shipment characteristics estimated from the sample of reasonably-priced shipments, however the STB chooses to define this sample, provides provides a valid estimate of the distribution of “reasonable” prices given any vector of observed shipment characteristics. The STB’s relative preference for reducing the probability of falsely finding that a reasonable shipment price is unreasonable versus reducing the probability of failing to reject that an unreasonable shipment price is reasonable, determines the percentile of the conditional distribution of reasonable prices that becomes the price benchmark for determining if the observed price for the shipment is excessive. As we demonstrate below, this process is very similar to choosing the critical value for a statistical hypothesis test.

### III. Estimating the Reasonable Price Conditional Distribution

This section describes our procedure for estimating the distribution of a reasonable price for a shipment conditional on the product and shipment characteristics. This conditional distribution is the essential input for computing the benchmark price used to determine whether an actual shipment price is “excessive.” Our approach is completely nonparametric and only relies on the existence a sample of “reasonable” shipment prices and product and shipment characteristics, such as the one available from the Waybill Sample compiled each year by the STB.

The remainder of this section first summarizes our methodology for estimating the conditional distribution of a reasonable price given the characteristics of the shipment.<sup>22</sup> We then briefly describe the Waybill data sample and how it is used to estimate this conditional distribution. Finally, we describe how the estimation process can be automated to update this conditional distribution each year with the new Waybill Sample.

#### III.1. Estimation Procedure

We want to estimate  $F(y|X)$ , the conditional distribution function of the  $y$ , the shipment price, given a vector  $X$  of  $J$  variables, the vector of product and shipment characteristics, using  $i = 1, \dots, N$  observations.<sup>23</sup> We utilize the Nadaraya (1964) and Watson (1964) kernel regression estimator of  $F(y|X)$  that accounts for stratified sampling of shipments in the Waybill data:

---

<sup>22</sup>Appendix A describes the technical details of our methodology. An important step in the estimation process described in Appendix A is the selection of the bandwidth for the kernel regression estimate of this conditional distribution.

<sup>23</sup>The method we use does not involve the smoothing of  $y$ . Another method would be to smooth  $y$  and get  $F(y|X)$  analytically by integrating  $f(y|X)$ . the conditional density of  $y$  given  $X$ , over  $y$ . We found this to induce more bias into our estimate of the conditional distribution particularly in the tail of the distribution, which as we demonstrate in Section IV, is the portion of the price distribution most relevant for computing our benchmark price.

$$\begin{aligned}\hat{F}(y|X, a) &= \frac{\frac{1}{N} \sum_{i=1}^N (EF_i) K_a(X - X_i) \mathbf{I}(y_i \leq y)}{\frac{1}{N} \sum_{i=1}^N (EF_i) K_a(X - X_i)} \\ &= \frac{\sum_{i=1}^N (EF_i) K_a(X - X_i) \mathbf{I}(y_i \leq y)}{\sum_{i=1}^N (EF_i) K_a(X - X_i)}\end{aligned}$$

where  $\mathbf{I}(y_i \leq y)$  is 1 if  $y_i$  is less than equal to  $y$  and 0 otherwise.  $EF_i$  is the expansion factor associated with the  $i^{th}$  observation giving the number of shipments in the population of annual shipments that has the same observable characteristics  $X$  as this shipment.

Kernel regression is a nonparametric method for estimating the conditional mean function of one element of a random vector, in this case  $I(y_i \leq y)$ , given the remaining elements of that random vector,  $X$ .<sup>24</sup> Note that the conditional expectation of  $I(y_i \leq y)$  given  $X_i$ ,  $E(I(y_i \leq y)|X_i)$ , is equal to  $F(y|X_i)$ . Therefore,  $\hat{F}(y|X, a)$  defined above is a consistent estimate of the population conditional distribution of  $y$  given  $X$  that accounts for the fact that a stratified random sample is used to estimate  $F(y|X)$ . In this case the kernel regression estimate of  $F(y|X)$  is a weighted average of the values of the indicator variables  $I(y_j \leq y)$  for  $j = 1, 2, \dots, N$ , where larger weights are applied to the  $I(y_j \leq y)$  with values of  $X_j$  that are closest to  $X$ . The formula for  $\hat{F}(y|X, a)$  given above computes this local smoothing estimator of  $F(y|X)$  for all possible values of  $X$  and  $y$  without imposing any functional form restriction on the conditional distribution of  $y$  given  $X$  beyond the fact that it is non-decreasing in  $y$  and takes on values between zero and one.

Given a sample of “reasonable” shipment prices, associated product and shipment characteristics, and expansion factors, computing the value of  $\hat{F}(y|X)$  for a potentially unreasonable shipment price and product and shipment characteristics pair  $(y, X)'$  requires computing the  $N$ -term summation shown above. Consequently, once the  $J$ -dimensional vector of smoothing parameters  $a$  described in Appendix A are chosen, the process of updating  $\hat{F}(y|X)$  with new data is straightforward to automate. Appendix A describes how the process choosing  $a$  can be automated as well, although if the new observations are similar to the existing data used to compute  $\hat{F}(y|X)$ , updating the value of  $a$  may be unnecessary.

### **III.2. Data**

The STB’s Carload Waybill Statistics (CWS) is the primary data source used to estimate the conditional distribution of the reasonable price given a shipment’s observed characteristics. Each year’s CWS consists of more than 500,000 stratified randomly sampled shipments with information on revenue, distance, shipment size, the identity of the railroads that pro-

---

<sup>24</sup>Pagan and Ullah (1999) provide an accessible introduction to this nonparametric conditional mean estimation procedure.

vided the service, and the expansion factor ( $EF$ ) for that shipment.

The CWS records also contain codes that were linked with Oak Ridge National Laboratory (ORNL) Rail Network files to allow shipper and receiver locations to be identified. Specifically, rail station records are identified by a Standard Point Location Code. These identifiers permit mapping of origin and destination stations into the CWS and the assignment of latitude and longitude values to each shipment origin and destination. These data, along with railroad network geographic information system data, were combined to identify locations of stations and shipment origins and destinations and to develop measures of railroad competition described below.<sup>25</sup> The data were also used in conjunction with the Port Series<sup>26</sup> data produced by the U.S. Army Corps of Engineers to measure the presence of water competition. The Port Series data indicate the location of ports on U.S. waterways along with the commodities handled by each port.

All rates from the CWS were adjusted to constant 2009 dollar values by using the quarterly gross domestic product price deflator available from Federal Reserve Economic Data through the Federal Reserve Bank of Saint Louis.<sup>27</sup>

We use the subsample of the CWS movements that the STB has deemed are competitively provided and therefore exempt from regulatory oversight to estimate the reasonable price conditional distribution. For all of the products we consider, this subsample is composed of the two classes of movements created by the Staggers Act: (1) exempted traffic and (2) contract movements.<sup>28</sup> When the Staggers Act was passed, our approach was not feasible because that all rates were subject to regulation. But, the Staggers Act allowed the regulatory authority to exempt traffic from maximum price regulation (49 USC §10502) and it allowed the use of confidential contracts which were not subject to regulation. Under partial deregulation, large classes of traffic were exempted by the ICC and contracts became widely used.

The legislation declared that the new regulatory policy would be to allow “competition and the demand for services to establish reasonable rates for transportation by rail.” (49 USC §10101 (1)). Regulators were instructed to be aggressive in fully exempting from any further regulatory control all traffic—truck-competitive traffic being the most obvious—for which regulation was “not needed to protect shippers from the abuse of market power.”<sup>29</sup>

---

<sup>25</sup><http://www-cta.ornl.gov/transnet/RailRoads.html>.

<sup>26</sup><http://www.navigationdatacenter.us/ports/ports.htm>.

<sup>27</sup><https://fred.stlouisfed.org/series/GDPDEF>

<sup>28</sup>Other definitions of reasonably-priced shipments could be used. For example, in an early version of this methodology reported in the National Academies of Sciences report, *Modernizing Freight Rail Regulation* we used exempted traffic and contract shipments with more than one railroad serving the origin or destination or water transport availability at the origin or destination. This definition of the sample of reasonably-priced shipments yielded similar to results to the ones reported in Section V.

<sup>29</sup>49 USC §10502. Although the exemption provision is not explicit in identifying trucks as the competition

Once it designated a class of traffic “exempt,” the ICC would no longer have control over the rates charged to shippers or the amount and quality of service made available to them.

For commodities that were not ruled exempt, a critical reform was the law’s legalization of confidential contracts between railroads and shippers. Any shipment moved under contract would be automatically excluded from any further regulation during the life of the contract; railroads would thus be free to tailor their rate and service offerings on a shipper-by-shipper basis.

The ability of a railroad to contract gave it substantial latitude to set rates differentially according to a shipper’s individual circumstances and willingness to pay. Railroads would not only be allowed to compete more aggressively for the newly exempted freight that is inherently competitive with trucks but would also be allowed to set tariff rates for the nonexempt bulk commodities at levels equivalent to the most rail-dependent shipper’s willingness to pay. While shippers with more transportation options would be expected to refuse to pay the higher rate, a railroad could simply negotiate a discounted contract rate with terms tailored to each shipper’s specific situation and willingness to pay. The price-differentiating railroad would now be able to set rates at levels that avoid pricing any traffic that makes a positive contribution to fixed cost recovery out of the market.<sup>30</sup>

Exempt traffic and contract shipments were designed to provide the railroads with an the opportunity to earn sufficient revenues for their long-term financial viability. Since the passage of the Staggers Act, the share of total shipments in the CWS designed as “exempt” or “contract” has grown continuously, which is major factor in explaining the improved financial condition of Class I railroads. This trend implies that the precision and quality of our estimated reasonable shipment price conditional distribution are likely to improve over time.

Nevertheless, shipments that are neither “exempt” nor “contract” and therefore subject to the Staggers Act provision to protect captive shippers from excessive shipment rates are likely to continue to exist. Therefore, a mechanism for determining whether a shipment rate is “excessive” will continue to be necessary. Our benchmark approach provides a low-cost alternative to the current approach to addressing this statutory mandate.

---

of interest, trucks are the only ubiquitous mode, and thus a commodity’s practical capability to be moved by truck became the de facto standard for deciding whether a commodity should be considered inherently competitive and granted a categorical exemption.

<sup>30</sup>As noted earlier, because of this incentive to extract rents but not price traffic out of the market, the efficiency loss from railroads having pricing freedom is expected to be minimal. Indeed, limited deadweight loss associated railroad pricing was found by Grimm and Winston (2000, p. 65).

#### IV. Choosing Benchmark Price for a Shipment

Our use of a price benchmark is different from the typical use of this construct in a regulatory proceeding. Price cap regulation typically specifies a maximum price or set of maximum prices that a price-regulated firm is allowed to charge for all of its products. These prices are designed to allow the firm an opportunity to recover its total cost of production through prudent operation. Yardstick regulation determines these maximum prices by using information from a group of "like" firms producing the same product. Again, the resulting price benchmark is used to set the maximum price that the firm can charge for its output.

Our application differs from these uses of a benchmark price because a growing share of shipments are provided at market-determined prices, whereas under price cap and yardstick regulation all of the firm's output is subject to this maximum price regulation. Our price benchmark only determines the level of an "excessive" or "unreasonable" price for shipments that are neither exempt nor contract, and therefore still subject to the Staggers Act regulatory mandate against excessive prices.

Setting the value of the "excessive price" for a shipment involves balancing two risks. The first is the risk of incorrectly determining that the observed shipment price is excessive when the shipment price is reasonable, and the second is the risk of failing to determine that a truly excessive price is in fact excessive. Because our benchmark price is derived from the conditional distribution of reasonable prices given shipment characteristics, we can build on the theory of statistical hypothesis testing to determine the value of the benchmark price. Specifically, our benchmark price is analogous to a critical value for the test of the null hypothesis that a shipment price is "reasonable" versus the alternative that it is "excessive."

If this null hypothesis is rejected, this raises the question what this "excessive" price should be reset to. This decision also involves balancing two risks. The first is the risk of setting this price too low and increasing the probability that the railroad does not recover sufficient revenues to cover its total production costs. The second is the risk that setting this price too high does not protect the shipper from excessive pricing. The Staggers Act anticipates this first risk by requiring the STB to make an annual determination of whether each Class I railroad is revenue adequate in the sense of earning sufficient revenues to recover its total cost of production.

This remainder of this section first presents the results of a Monte Carlo experiment to determine the value of the benchmark price that optimally balances—in the sense described below—the risks of failing to reject the hypothesis that a truly excessive price is reasonable versus the risk of falsely rejecting this null hypothesis for a price that is truly reasonable. We then use the results of this Monte Carlo study to inform our choice of the value of the benchmark price for our assessment of the impact on annual railroad revenues of various

choices of the price that the actual price is reset to (the “reasonable” price for the shipment) if it determined to be “excessive” using data from four classes of products from the CWS data.

#### ***IV.1. Monte Carlo Experiment on the Selection of the Benchmark Price***

In order to study the impact of the choice the value of the benchmark price on the probability of each type of misclassification error, we require an environment where we know with certainty whether a shipment price is competitively determined. We would also like this environment to have a realistic amount of variation in the price of a competitively provided product due to cost differences for supplying this product for the same realization of demand conditions. Conversely, we would also like the environment to have a realistic amount of variation in the price of competitively provided products due to demand differences for the same realization of the cost of supplying this product.<sup>31</sup>

For our purposes of our Monte Carlo study, we assume that a number of hypothetical railroads supply  $i = 1, \dots, N$  shipments, each with demand

$$D_i(p) = Ap^{-\alpha_i}$$

where  $\alpha_i = z_i\delta + \eta_i$ . The demand shifters,  $z_{ij}$ ,  $j = 1, 2, \dots, M$  are assumed to be independent and identically uniformly distributed,  $U(-1, 1)$ , random variables. The dimension for the demand shifters,  $M$ , was chosen to achieve a realistic level of variation in market prices for a given cost function realization for the railroads. We found that  $M = 4$  was sufficient to achieve this goal. Define  $z_i = (z_{i1}, \dots, z_{iM})' \in \mathbb{R}^M$  and

$$\delta = \left(\frac{1}{4}, \dots, \frac{1}{4}\right)' \in \mathbb{R}^M \quad \text{and} \quad \eta_i \sim U(6, 7).$$

The supports of the distribution of the demand shifters,  $z_{ij}$ , and values of the elements of  $\delta$  were selected to yield market prices with “competitive” markups over marginal costs for all realizations.

For the railroads’ cost function, let  $C(q_1, q_2, \dots, q_N) = \sum_{i=1}^N [w_i\gamma + \epsilon_i]q_i$ , where  $w_i$  is a  $K$ -dimensional vector of cost shifters. We draw the  $w_{ij}$   $j = 1, 2, \dots, K$  as independent and identically distributed  $U(-1, 1)$  random variables. Define  $w_i = (w_{i1}, \dots, w_{iK})' \in \mathbb{R}^K$  and let  $\epsilon_i \sim U(4, 5)$ . Set

$$\gamma = \left(\frac{1}{4}, \dots, \frac{1}{4}\right)' \in \mathbb{R}^K.$$

---

<sup>31</sup>We ran the Monte Carlo experiment described below for a variety of specifications of the dimensions and support of the demand and supply shifters and the marginal impacts of these demand and supply shifters on the elasticity of demand and marginal cost. All of these results support our conclusions about the appropriate choice the benchmark price from percentiles of the conditional distribution of reasonable prices given shipment characteristics.

We found that setting  $K = 5$ , setting support for the distributions of the demand shifters and values of the elements of  $\gamma$  was sufficient to obtain a realistic variation in market prices for a given demand function realization. The variation in the values of  $w_{ij}$  is chosen so that there are both high and low price competitive outcomes because of high and low values of marginal cost caused by variation in  $w'_i\gamma + \epsilon_i$ .<sup>32</sup>

Assuming the railroads set each shipment price,  $p_i$ , to maximize the sum of profits over the  $N$  shipments:

$$\pi(p_1, p_2, \dots, p_N) = \sum_{i=1}^N D_i(p_i)p_i - C(D_1(p_1), D_2(p_2), \dots, D_N(p_N)),$$

yields prices for each of the  $i = 1, 2, \dots, N$  shipments equal to

$$p_i = \left( \frac{-(z_i\delta + \eta_i)}{-(z_i\delta + \eta_i) + 1} \right) (w'_i\gamma + \epsilon_i) \quad (1)$$

Equation (1) demonstrates that variations in the markups over marginal cost are driven by variation in the values of the  $z_{ij}$  and variations in marginal cost are driven by variation in the  $w_{ij}$ . The combination of these two observable sources of random variation along with the two unobservable sources of random variation in  $\eta_i$  and  $\epsilon_i$  produces a realistic conditional distribution of shipment prices given the  $z_{ij}$  and  $w_{ij}$ .

Translating the variables of this economic model into our notation for the conditional distribution of reasonable prices let,  $X_i = (z'_i, w'_i)'$ , equal the set of conditioning variables and  $y_i = \ln(p_i)$ , natural log of  $p_i$ .<sup>33</sup> We then use these  $N$  observations of  $y_i$  and  $X_i$  to estimate the conditional distribution of reasonable prices given the shipment characteristics,  $\hat{F}(\ln(p)|X, a)$ , following the kernel regression procedure described in Section III.

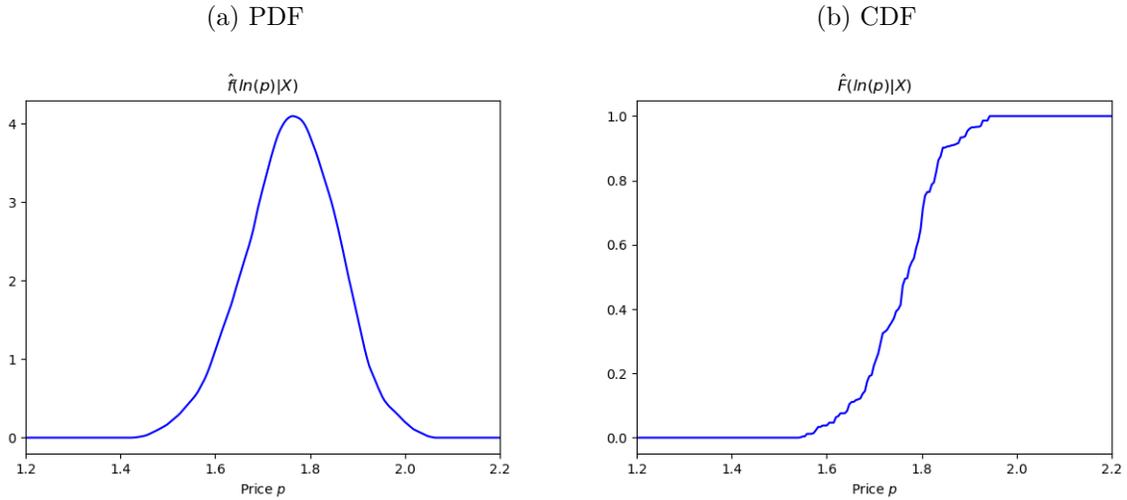

Figure 1 presents the estimated values of  $\hat{f}(\ln(p)|X, a)$  and  $\hat{F}(\ln(p)|X, a)$  for  $N = 1,000$  observations, for the sample mean of the  $X_i$ . Although there is significant variation in prices,  $p_i$ , the variation in the markup of price over the marginal cost caused by variation in the values of  $z_{ij}$  is within the range of what we consider to be reasonable. The majority of the variation in prices is due to variation in marginal costs caused by variation in the observed cost shifters,  $w_{ij}$ , and variation in the unobserved values of  $\eta_i$  and  $\epsilon_i$ . For this reason, we assume that all of the prices that arise from solving equation (1) are the result of "effective"

<sup>32</sup>We experimented with a number of different parameter values for the demand and cost functions and the dimensions of the demand and supply shifters. Our conclusions about the percentile of the conditional distribution of reasonable prices that minimizes the sum of squared misclassification errors is largely invariant to these modeling choices.

<sup>33</sup>We estimate the cumulative distribution of the natural logarithm of price in recognition of the fact that prices are positive and the distribution is positively skewed.

competition and are therefore truly "reasonable."

Figure 1: Conditional Density and Distribution of Logarithm of Reasonable Prices Given  $X$

Our choice of the benchmark price is equivalent to selecting the value of the percentile of the conditional distribution of reasonable prices given shipment characteristics beyond which any observed price would be deemed "unreasonable" or "excessive." Suppose  $p^*$  is the price of a potentially "excessive" priced shipment with characteristics  $X^*$ . If  $1 - \alpha$ , for  $1 > \alpha > 0$ , is the percentile of the distribution of  $\hat{F}(p|X)$  beyond which prices are deemed to be excessive, then  $PB(\alpha, X^*)$  solves the equation  $1 - \alpha = F(PB(\alpha, X^*))$ . If  $p^* > PB(\alpha, X^*)$ , then the null hypothesis that the observed shipment price,  $p^*$  is "reasonable" would be rejected. An equivalent decision rule is  $\hat{F}(p^*|X^*) > 1 - \alpha$ , then this null hypothesis would be rejected.

The Monte Carlo samples of truly "reasonable" and truly "excessive" prices used to determine the "optimal" value of  $\alpha$  are constructed as follows. We repeat the process of drawing observations of  $(z_i, w_i, \eta_i, \epsilon_i)$  for  $i = 1, 2, \dots, \mathbf{Q}$ , and compute  $p_i$  using equation (1) for all  $i$ . Then, for every  $k$  values of the  $p_i$ , we compute an "excessive price,"  $\tilde{p}_i$  and replace  $p_i$  with  $\tilde{p}_i$ . The processes used to compute these "excessive prices" are described below.

For each  $i = 1, 2, \dots, \mathbf{Q}$  in this test sample, define

$$\begin{aligned} I_i &= 1 \text{ if observation of } p_i = \tilde{p}_i \\ &= 0 \text{ otherwise.} \end{aligned}$$

This indicator variable is equal to 1 if the  $i^{\text{th}}$  price observation is truly competitive and 0 if this observation is truly non-competitive.

For each  $(p_i, z_i, w_i)$  combination in the test sample, we compute  $\hat{F}(p_i|z_i, w_i)$  using the reasonable price distribution estimated from the  $N = 1,000$  competitive price draws. We

then find the value of  $\alpha$  which minimizes the sum of squared misclassification errors:

$$\sum_{i=1}^{\mathbf{Q}} (I_i - \hat{I}_i)^2 \quad (2)$$

where  $\hat{I}_i$  is determined by the rule  $\hat{I}_i = 1$  if  $\hat{F}(p_i, z_i, w_i) > 1 - \alpha$ , and 0 otherwise. Depending on the value  $\alpha$ , the value of  $\hat{I}_i$  indicates whether the  $i^{\text{th}}$  price exceeds the value of  $PB(\alpha, X)$ , the benchmark price for a shipment with characteristics  $X$  and that value of  $\alpha$ . Ideally, we would like  $\hat{I}_i = I_i$  when  $I_i = 1$  and  $I_i = 0$ , meaning that when the price is truly “reasonable” it does not exceed the benchmark price and when it is truly “unreasonable” it does exceed the benchmark price. This would make our objective function equal zero for all observations. Note that both types of misclassification errors,  $\hat{I}_i = 0$  when  $I_i = 1$  and  $\hat{I}_i = 1$  when  $I_i = 0$ , contribute the same value, 1, to the objective function. Solving for the value of  $\alpha$  that minimizes (2) is the equivalent of finding the benchmark price function,  $PB(\alpha, X)$ , that minimizes the sum of squared misclassification errors for observations  $(y_i, X_i)'$  in our test sample of “reasonable” and “unreasonable” prices.

To compute “excessive” prices in our test sample, we change the distribution of  $\eta_i$ . We let

$$\tilde{p}_i = \left( \frac{-(z_i\delta + \tilde{\eta}_i)}{-(z_i\delta + \tilde{\eta}_i) + 1} \right) (w_i'\gamma + \epsilon_i)$$

where  $\tilde{\eta}_i \sim U(m, n)$ . For all scenarios,  $\eta_i \sim U(6, 7)$  for competitive observations. We alter the distribution of  $\tilde{\eta}_i$  starting with a distribution of  $\tilde{\eta}_i$  with a support that has the same range but is significantly lower than the support of  $\eta$ . The support of  $\tilde{\eta}_i$  has the same range but is closer to the support of  $\eta_i$  across the scenarios we consider. The closer the support of  $\tilde{\eta}_i$  is to the support of  $\eta_i$ , the more likely it is that our procedure will mistakenly classify “reasonable” prices as “excessive” and “excessive” prices as “reasonable.”

For all of the scenarios, we set  $\mathbf{Q} = 3,000$  and  $k = 5$ , which implies a total of 600 “excessive” prices in each 3,000 observation test sample. The second column of Table 1 presents the value of  $\alpha$  that minimizes the sum of squared misclassification errors for each distribution of  $\tilde{\eta}_i$  listed in the first column of the table. The third column of the table lists the number of Type I errors (reasonable prices classified as “excessive” observations) and the fourth column the number of Type II errors (“excessive price” observations classified as reasonable) for each distribution of  $\tilde{\eta}_i$ . The final column gives the percentage of the 3,000 test sample observations that are misclassified (the sum of Type I and II errors) for each distribution of  $\tilde{\eta}_i$ .

As the support of the distribution of  $\tilde{\eta}_i$  comes closer to the support of the distribution  $\eta_i$ ,

the distribution of “excessive” prices is closer to the distribution of “reasonable” prices. The percent of observations in our test sample that are misclassified also rises. However, even for the case that the supports of  $\tilde{\eta}_i$  and  $\eta_i$  are virtually the same,  $(5.75, 6.75)$  versus  $(6, 7)$ , less than 20 percent of the observations in the test sample are misclassified. Finally, for all of the scenarios considered, the value of  $\alpha$  that minimizes the sum of squared misclassification errors lies in the interval  $(0.0627, 0.0133)$ .

These results demonstrate that if the support of the distribution of reasonable prices and the support of the distribution “excessive prices” are closer to together, the smaller is the value of the  $\alpha$  that minimizes the sum of the squared misclassification errors. These Monte Carlo results suggest that in practice the value of  $\alpha$  is unlikely to be larger than 0.06 and smaller than 0.01.

Figures 2 to 7 contains graphs of the values of  $\hat{f}(\ln(p)|X)$  and  $\hat{F}(\ln(p)|X)$  for all prices in our test samples for each of the six scenarios for the support of  $\tilde{\eta}_i$  we consider. The red dots are the truly unreasonable observations and the blue dots are the truly reasonable observations. These graphs and Table 1 illustrate that the major cost in terms of misclassification errors as the supports of the distributions of reasonable and unreasonable prices come closer is a substantial increase in Type II errors—failing to find that an unreasonable price is “excessive.” For all of the scenarios considered, the frequency of Type I errors—concluding that a reasonable price is “excessive” remains very low.

Table 1: Monte Carlo Results for Choice of Optimal Value of  $\alpha$

$\tilde{\eta}_i \sim$	$\alpha$	Type I Error	Type II Error	% Misclassified
$U(3.75, 4.75)$	0.0478	34	339	10.2
$U(4, 5)$	0.0627	58	365	10.2
$U(4.5, 5.5)$	0.0478	34	481	14.9
$U(5, 6)$	0.0303	17	553	17.9
$U(5.5, 6.5)$	0.0133	2	586	19.5
$U(5.75, 6.75)$	0.0133	2	590	19.6

## V. Determining a “Reasonable” for a Shipment

Using the above results, we now implement our benchmark pricing procedure using actual data from the CWS in order to determine the appropriate “reasonable price” to use if an actual price is found to be “excessive.” To this end, we estimate separate conditional distributions for four broad commodity groups: petroleum products, farm products, coal, and chemical products. We then apply our benchmark price approach to all potential “unreasonable” prices for several values of  $\alpha$  less than or equal to 0.05. We then consider the total revenue implications of resetting any excessive prices to various “reasonable” price levels and the average amount of regulatory relief our procedure provides to shippers facing

“excessive” if these prices are reset to various features of the reasonable price distribution for that shipment.

These reasonable price conditional distributions could be estimated for more commodities and for narrower product groups (e.g., grain, hazardous materials) as long as there are sufficient observations to obtain credible estimates. Once this conditional distribution has been estimated for each commodity, the STB could use it to determine whether a shipper is being charged an “excessive price” for a movement or set of movements following the procedure described above given the shipment characteristics and a value of  $\alpha$ . As we discuss below, the results from our Monte Carlo study imply that the value of  $\alpha$  could be different for different commodities depending on the location of the support of the distribution reasonable prices versus the location of the support of the distribution of “excessive” prices.

A number of commenters on a previous draft raised the point that railroads would likely change their pricing strategy for shipments that go into the computation of the conditional distribution of reasonable prices given shipment characteristics. However, this response to the implementation of our price benchmark approach implies that railroads are not currently maximizing the static profits they earn from pricing these shipments. A railroad changing its pricing behavior in response to the implementation of our benchmark price mechanism could maximize the discounted present value of its expected profits, if giving up some profits in the current period achieves a large enough increase in expected profits in future periods. However, we believe that our approach to choosing the benchmark price makes railroads unlikely to change their behavior. As shown in Section IV, the benchmark price is an extreme percentile of the conditional distribution of prices given shipment characteristics. Even if railroads increase prices on the vast majority of their reasonably-priced shipments, this behavior is unlikely to impact significantly the upper  $\alpha$  percentile of this conditional distribution for values of  $\alpha$  in the range of 0.05 to 0.01 recommended by our Monte Carlo study. This logic implies that the expected payoff to the railroad in the future is unlikely to compensate for lost profits in the current period by setting a higher shipment price.

Estimating our conditional reasonable price distribution relies primarily on data from the CWS. The dependent variable  $y_i$  is the natural logarithm of the average revenue per ton mile (ARTM) for the shipment deflated by the gross domestic product price deflator. This variable is the revenue received from a shipment divided by the product of the number of tons in the shipment and the distance traveled. Revenues are the sum of freight revenues (transportation-related revenues), miscellaneous charges, and fuel surcharges.<sup>34</sup> In the

---

<sup>34</sup>Fuel surcharges were introduced by railroads in 2003 but were reported in different CWS fields by different railroads. Some railroads included these surcharges in the freight revenue field and others included them in the miscellaneous revenue field. From 2009 forward, CWS has had a separate field for fuel surcharges. Therefore, our solution is to use total revenues, including these fuel surcharges, for the shipment as our

calculation for ton-miles, the variable “billed weight” was used for tons, and distance was calculated as the “total miles traveled for the shipment.”

The elements of  $X_i$ , the vector of shipment characteristics are: (1) shipment distance ( $X_1$ ), (2) shipment size (number of cars) ( $X_2$ ), (3) the number of railroads involved in the movement ( $X_3$ ), (4) the number of Class I railroads within 10 miles of the origin ( $X_4$ ), (5) the number of Class I railroads within 10 miles of the destination ( $X_5$ ), (6) a dummy to indicate whether the shipper owns the cars ( $X_6$ ), and (7) a dummy to indicate that there is no water port within 50 miles of the origin ( $X_7$ ), and (8) a dummy to indicate that there is no water port within 50 miles of the destination ( $X_8$ ). Additional variables can be added to the vector of shipment characteristics,  $X$ . The elements of  $X$  selected for this implementation were based on two factors: (a) previous empirical research on the determinants of shipment rates and (b) the availability of the variables in the CWS and other publicly available data sets.<sup>35</sup> All of the continuous variables—distance, size, number of railroads—are measured in natural logarithms, to make their marginal distributions more symmetric. In preliminary versions of this analysis, we experimented with different distances for constructing  $X_4$ ,  $X_5$ ,  $X_7$ , and  $X_8$ , and obtained quantitatively similar empirical results. Finally, fixed effects are included for the year of the movement, for the primary railroad in the movement, and for the five-digit Standard Transportation Commodity Code (STCC) categories. Each shipment in the CWS has an expansion factor,  $EF_i$ , that gives the STB’s estimate of the number of shipments in the population of annual shipments with same observable characteristics as this shipment.

These conditioning variables are chosen based on availability in the CWS and past econometric studies that examine how rail rates relate to shipment characteristics such as distance, shipment size, and number of railroads involved in the shipment, as well as various measures of intramodal and intermodal competition (Boyer 1987; Barnekov and Kleit 1990; McFarland 1989; Burton 1993; Wilson 1994; Dennis 2000; Schmidt 2001; MacDonald 1987; MacDonald 1989; Grimm et al. 1992; Burton and Wilson 2006).<sup>36</sup>

To implement our nonparametric conditional distribution estimator, we first divide the vector  $X$  into two groups of variables: continuous ( $X_c$ ) and binary ( $X_d$ ) (this also includes the categorical variables used for fixed effects). Using the dataset composed of observations classified as being reasonably priced (in this case exempt and contract shipments), we regress  $y$  and the columns of  $X_c$  on  $X_d$  and take the residuals,  $e_p$  and  $e_X$ . The each variable in  $e_X$  is then scaled by subtracting its mean and dividing by its standard deviation.

---

shipment revenue variable.

<sup>35</sup>See, for example, MacDonald (1987 and 1989) and Wilson (1994).

<sup>36</sup>Shipment size is measured by carloads in the shipment. It is common practice for railroads to offer lower rates for multiple-car shipments.

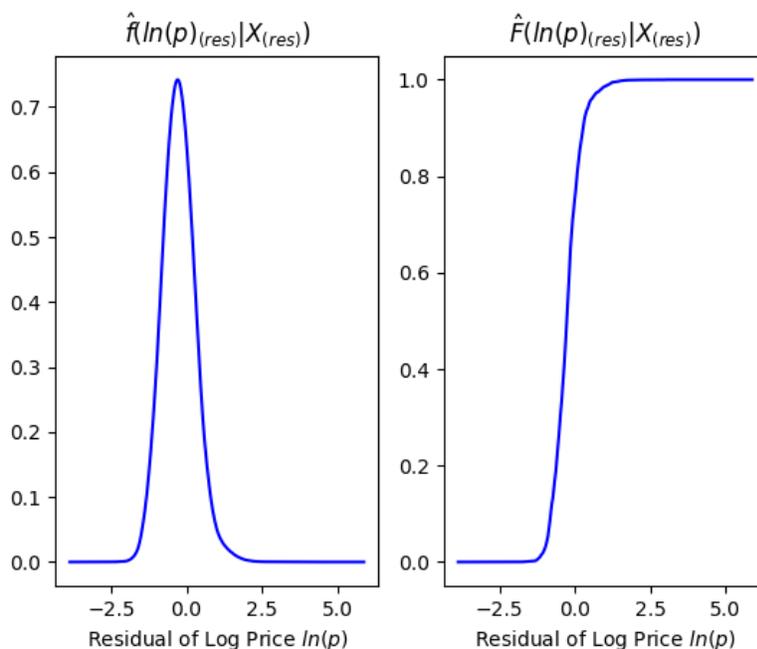

We then estimate the distribution  $\hat{F}(e_p|e_X)$  using the process described above. Then, using the estimated coefficients from the regressions on the sample of reasonable shipments, we compute  $e_p$  and  $e_X$  for the potentially unreasonably-priced routes and then scale the variables in  $e_X$  using the mean and standard deviation from the reasonably-priced sample. We compute  $\hat{F}(e_p|e_X)$  for these observations, and classify observations as unreasonable using  $\alpha$ , as described above.<sup>37</sup>

Results for estimating this conditional reasonable price distribution model using petroleum products, farm products, coal, and chemical products data from the years 2000 to 2013 from the CWS are presented below.

### ***Petroleum Products***

There are 50,340 observations in the reasonable price dataset, and 36,073 in the potentially unreasonable dataset. The following figures display the estimated distributions  $\hat{f}(e_p|e_X)$  and  $\hat{F}(e_p|e_X)$ , for the sample mean of  $X$ .

Figure 8: Conditional Density and Distribution for a fixed  $X$

Tables 2 and 3 compute the percent of observations found to exceed the benchmark price for that value of  $\alpha$  in our test samples for petroleum products for each year from 2000 to 2013. The first column gives the year of the sample. The second column the sum of the

<sup>37</sup>We also experimented with the Li and Racine (2008) procedure for nonparametric conditional cumulative distribution function estimation with mixed categorical and continuous data and obtained similar results. This procedure is more computationally intensive and requires more user-selected parameters, which would make it more challenging to implement in a regulatory process than our procedure.

expansion factors for all shipments that year and the third column is the sum of expansion factors for shipments that exceed the price benchmark in that year,<sup>38</sup> The final column is the ratio of the third column divided by the second column expressed as a percentage. The first line of each table gives the totals for each column for all of the years in the table. Across all years and for both  $\alpha = 0.05$  and  $\alpha = 0.01$  the frequency of excessive observations is less than or equal to 5 percent.

Table 2: Petroleum Products Estimated Population Classifications by Year,  $\alpha = 0.05$

Year	Total Obs	# "Excessive"	% "Excessive"
	1376558	50970	3.703
2000	150276	3394	2.259
2001	120566	3952	3.278
2002	84216	4052	4.811
2003	82932	2856	3.444
2004	80452	3120	3.878
2005	94296	2952	3.131
2006	108212	5456	5.042
2007	102844	5076	4.936
2008	94992	3736	3.933
2009	88812	3700	4.166
2010	81804	3872	4.733
2011	87312	3328	3.812
2012	98588	2368	2.402
2013	101256	3108	3.069

In Table 4, we assess the impact of resetting shipment prices that are deemed to be excessive to different features of the conditional reasonable price distribution on the revenues railroads earn from moving petroleum products over our sample period of 2000 to 2013. We consider three possible “reasonable” prices for shipments that have been deemed to be excessive using our benchmark price for given value of  $\alpha$ . First, we re-set “excessive” prices to the conditional mean of the reasonable price distribution. Second, we set it equal to the conditional median of the reasonable price distribution. Finally, we set it equal to  $PB(\alpha, X)$  the benchmark price for that shipment. We show the percent in change total revenues over our sample period associated with replacing each “excessive” price with that “reasonable” price using the benchmark price  $P(\alpha, X)$  for  $\alpha = 0.1, 0.05, 0.01$ .

Particularly, for the “reasonable” price set equal to our benchmark price, the aggregate revenue implications for railroads of resetting the actual price to this price are less than 1.2

<sup>38</sup>As discussed earlier, the expansion factor for a shipment gives the estimated number of waybills in the population of shipments that the each waybill in the CWS sample represents.

Table 3: Petroleum Products Estimated Population Classifications by Year,  $\alpha = 0.01$

Year	Total Obs	# "Excessive"	% "Excessive"
	1376558	12540	0.911
2000	150276	404	0.269
2001	120566	1092	0.906
2002	84216	1256	1.491
2003	82932	748	0.902
2004	80452	360	0.447
2005	94296	972	1.031
2006	108212	1264	1.168
2007	102844	1160	1.128
2008	94992	972	1.023
2009	88812	996	1.121
2010	81804	1104	1.350
2011	87312	836	0.957
2012	98588	732	0.742
2013	101256	644	0.636

percent for  $\alpha$  less than or equal to 0.05. Even for "reasonable" prices equal to the conditional mean and median, the revenue reductions are less than 3.1 percent for  $\alpha$  less than or equal to .05.

To assess the extent to which shippers obtain rate relief by resetting the actual price to one of these three "reasonable" prices, we compute the average difference between the actual "excessive" price and the "reasonable" price for each of our measures of a "reasonable" price. Table 5 reports the average value of these price differences for the three "reasonable" price measures for values of  $\alpha = 0.1, 0.05, 0.01$ . The last line of the table reports that average value of actual prices for all of the prices in the test sample deemed to be "excessive" for that value of  $\alpha$ .

These results demonstrate that even for the case of the "reasonable" price equal to our benchmark price, the average price change from the actual price to the "reasonable" price are a significant fraction of the average price that is deemed to be "excessive." For example, for the case of  $\alpha = 0.05$ , the average "excessive" price is \$18.38 and the average difference between the actual price and the "reasonable" price using our benchmark price is \$5.25, which implies an average price reduction of more than 28 percent.

Table 4: Petroleum Products Percent Revenue Changes from Different “Reasonable” Prices

	$\alpha = 0.1$	$\alpha = 0.05$	$\alpha = 0.01$
% change using mean $p$	-3.19	-2.20	-0.82

Average $p$ of unreasonable obs	13.59	18.38	28.56

### ***Farms Products***

For Farm Products there are 53,205 observations in the reasonable price dataset, and 115,337 in the potentially unreasonable price dataset. Tables 6 and 7 reproduce tables 2 and 3 for farm products. Across all years and for both  $\alpha = 0.05$  and  $\alpha = 0.01$  the frequency of excessive observations is less than or equal to 2.7 percent.

In Table 8, we show the percent change in total revenue for our sample period if we were to change prices that were classified as “excessive” to each of the three features of the conditional distribution of reasonable prices described above. In this case, resetting “excessive” prices to any of our three features of the “reasonable” price distribution implies a less than 1.3 percent revenue reduction for  $\alpha$  less than or equal to 0.05.

Table 9 reports the average value of these price differences for the three “reasonable” price measures for values of  $\alpha = 0.1, 0.05, 0.01$ . These results demonstrate that even for the case of the “reasonable” price equal to our benchmark price, the average price changes from the actual price to the “reasonable” price are a significant fraction of the average price that is deemed to be “excessive.” For example, for the case of  $\alpha = .05$ , the average “excessive” price is \$1.58 and the average difference between the actual price and the “reasonable” price using our benchmark price is \$0.53, which implies an average price reduction of more than 34 percent.

### *Coal*

For coal, there are 285,976 observations in the reasonable price dataset, and 158,068 in the potentially unreasonable price dataset. Tables 10 and 11 break the classifications down by the year of the observation and use the CWS expansion factors to estimate population values for the number of “excessive” prices and frequency of “excessive” prices each year. For both  $\alpha = 0.05$  the annual frequency of excessive observations is as high as 26 percent in 2006. With  $\alpha = 0.01$  the annual frequency of excessive observations never exceeds 9 percent.

A number of trends on the United State coal sector caused the dramatic changes in the estimated annual population of shipments shown in the second column of Tables 10 and 11. First, an increasing share of coal deliveries came from surface mines west of the Mississippi River. These shipments involved a substantially larger number of coal cars. Unit trains that move western coal can involve hundreds of coal cars, whereas earlier movements involving eastern coal from underground mines often involved less than ten coal cars. These trends in the United States coal industry explain the substantial drop in the estimated population number of shipments over time and the large drop between 2005 and 2006.

Because coal shipments are fairly homogeneous, there is likely to significant overlap between the support of the distribution of reasonable prices and the support of the distribution of unreasonable prices. From the results of our Monte Carlo study, this argues in favor of a value of  $\alpha$  in the neighborhood of 0.01.

In Table 12, we show the percent change in revenue if we were to change prices that were classified as unreasonable for the three features of the conditional distribution of reasonable prices. In this case, resetting “excessive” prices to any of the three features of the “rea-

sonable” price distribution for the case of  $\alpha = 0.05$  implies at least a 3.5 percent reduction in annual revenues. For the case of  $\alpha = 0.01$ , the largest percentage reduction in annual revenues is 3.4 percent, which provides a further evidence that  $\alpha = 0.01$  is likely to be the appropriate choice of  $\alpha$  for the coal.

Table 13 reports the average value of the “excessive” price minus the “reasonable” price for the three “reasonable” price measures for values of  $\alpha = 0.1, 0.05, 0.01$ . These results provide additional evidence that there is significant overlap between the supports of the distributions of “excessive” prices and reasonable prices. The average price changes from the actual price to a “reasonable” price set equal to our benchmark price is 5 cents for  $\alpha = 0.05$ . The average “excessive” price for this scenario is 25 cents, which implies an average price reduction of 20 percent, which is a significantly lower percentage change than is the case for petroleum products or farm products.

### ***Chemical Products***

For Chemical Products there are 356,187 observations in the reasonable price dataset, and 197,624 in the potentially unreasonable price dataset. Tables 14 and 15 break the classifications down by the year of the observation and use the CWS expansion factors to estimate population values of the number and the percent of excessive prices each year. For both  $\alpha = .05$  the frequency of excessive observations is never higher than 6.8 percent, and is typically in the range of 3 to 4 percent. With  $\alpha = 0.01$  the frequency of excessive observations never exceeds 1.2 percent.

Because chemical products shipments are likely to be more heterogeneous than coal shipments, there is less overlap between the support of the distribution of reasonable prices and the support of the distribution of unreasonable prices than is the case for coal. From the results of Monte Carlo study, this argues in favor of a value of  $\alpha$  in the neighborhood of 0.05.

In Table 16, we show the percent change in revenue if we were to change prices that were classified as unreasonable for the three features of the conditional distribution of reasonable prices. Resetting “excessive” prices to any of our three features of the distribution of “reasonable” prices for the case of  $\alpha = 0.05$  implies at least a 3.2 percent reduction in annual revenues. For the case of  $\alpha = 0.01$ , the largest percentage reduction in annual revenues is less than one percent, which provides a further evidence that  $\alpha = .05$  may be the appropriate choice for the chemicals.

Table 17 reports the average value of the “excessive” price minus the “reasonable” price for the three “reasonable” price measures for values of  $\alpha = 0.1, 0.05, 0.01$ . These results provide additional evidence that there is less overlap between the supports of the distributions of “excessive” prices and reasonable prices for chemicals than for coal. The average price changes from the actual price to a “reasonable” price set equal to our benchmark price is \$3.31 for  $\alpha = .05$ . The average “excessive” price for this value of  $\alpha$  is \$11.75, which implies an average price reduction of 30 percent, which is in the neighborhood of the values obtained for petroleum products and farm products.

Average $p$ of unreasonable obs	8.55	11.75	20.04

A number of conclusions emerge from our Monte Carlo study and the application of our benchmark price to data from the CWS. First, our Monte Carlo study finds that values of  $\alpha$  less than 0.06 and greater than 0.01 appear to minimize the sum of squares of misclassification errors for the types of conditional distributions of reasonable prices and conditional distributions of “excessive” prices likely to be encountered in practice. Second, for these values of  $\alpha$ , the vast majority of shipment prices in our Monte Carlo test sample are correctly classified as reasonable when they are truly reasonable.<sup>39</sup> Third, for these values of  $\alpha$ , even resetting the “excessive” price to the conditional mean or conditional median of the reasonable price distribution is likely to have a relatively small adverse impact on the revenues earned by shippers for the four product categories considered. Fourth, resetting the value of an “excessive” price to the value of our benchmark price has the smallest adverse impact on railroad revenues. Fourth, for all products we find that resetting “excessive” prices to any of our three features of the “reasonable” price distribution produces economically meaningful price reductions for the affected shippers. For  $\alpha$  less than 0.05, the smallest average percentage price reduction for mitigated shipments relative to the average actual “excessive” price across the four product groups is 20 percent.

Taken together, these results suggest that our benchmark pricing approach can be a low administrative cost approach for the STB to carry out its statutory mandate to protect shippers from excessive prices, while at the same time not adversely impacting the ability of the railroads to achieve the aggregate revenues necessary for their long-term financial viability.

---

<sup>39</sup>When the supports of the distribution of unreasonable prices and reasonable prices overlap, most of the misclassification errors are due to classifying unreasonable prices as reasonable prices.

## ***VI. Potential Use of Benchmark Price Mechanism in Regulatory Process***

There are a variety of ways to use the benchmark price mechanism to carry out the STB's mandate to protect captive shippers from "excessive" prices. The benchmark price approach could replace the  $R/VC \leq 180$  test for an "excessive" price as the first step in the rate relief process. Alternatively, the benchmark price could supplement the  $R/VC < 180$  test to ensure that failure of this test is due to the shipper facing a "market dominant" railroad. Finally, features of the reasonable price distribution could be used to determine the reasonable price than an excessive shipment price would be reset to in the event that an excessive price finding was made.

Using the benchmark price approach to replace the  $R/VC \leq 180$  test for an "excessive" price would end the STB's reliance on URCS "variable cost" measures in making an "excessive" price finding. This would likely require legislation to change this step in the "excessive" price determination process. The need for legislative action raises the question of who should set the value of  $\alpha$  that determines the value of the benchmark price. Similar to the case of the  $R/VC \leq 180$  test, the value of  $\alpha$  could be set in the legislation that implements the benchmark price. Alternatively, the law could provide legislative guidance to the STB in setting the value  $\alpha$ . For example, the law could direct the STB to set  $\alpha$  to minimize an estimate of the sum of squared misclassification errors.

As is the case under the current rate relief process, a price that exceeds the benchmark level would not be subject to regulatory relief unless the STB also determines the rate charged is the result of a market dominance. The benchmark price mechanism can also provide useful input to this stage of the rate relief process. A railroad that sets a price that exceeds the benchmark level for its product and shipment characteristics could be required to identify the factors not included in  $X$ , the vector of observed product and shipment characteristics, that "explains" this high price. Conversely, the shipper can argue that these factors do not "explain" the high price charged. Failure to provide convincing evidence that unobserved factors explain an actual price above the benchmark level would result in a finding of market dominance.

This use of the benchmark price approach supports one of the recommendations for reform of the rate relief process from the NAS report, *Modernizing Freight Rail Regulation*, to use final offer arbitration to determine the "reasonable" shipment price if the railroad is found to charge a price that exceeds the benchmark price and that price is found to be the result of a dominant railroad. The arbitrator could determine whether the factors proposed by the railroad "explain" the higher price and therefore the shipper is not entitled to rate relief.

This arbitration process also could provide input to the computation of future benchmark

prices. If a certain factor not included in the vector of observed characteristics,  $X$ , used to compute the benchmark price is found by the arbitrator to "explain" the higher price, the STB could require data on that factor to be compiled for all future shipments sampled for the Waybill data. This factor could then be incorporated in the vector of observed characteristics,  $X$ , used to compute the conditional distribution of reasonable prices.

For example, railroads argue that hazardous materials are more expensive to move and therefore charge higher prices to ship these materials. Based on the result of arbitration processes on this issue, the STB could require shippers to report shipment characteristics in their Waybill data that describe the dimensions of the hazardous materials in the shipment and these observable factors could be incorporated into the vector of product and shipment characteristics,  $X$ , used to compute the conditional distribution of reasonable prices.

Finally, if the STB or an arbitrator determines that a shipment price is excessive, then a reasonable price must be set for the shipment and refunds determined. From results of our average "excessive" minus "reasonable" price analysis, the conditional distribution of the reasonable price distribution for this shipment could provide useful information to the STB or an arbitrator in determining this reasonable price.

A final issue that the benchmark price approach can address is the impact of the selection of the feature of the "reasonable" price distribution on the annual revenue adequacy of the railroad. As shown in Section V, setting the "reasonable" price using a percentile of the conditional distribution of reasonable prices allows an analysis of the annual revenue implications of different choices of  $\alpha$  for determining this reasonable price. Smaller values of  $\alpha$  imply a larger value of the "reasonable" price and therefore a smaller reduction in annual revenues from resetting "excessive" prices.

This logic suggests another factor to consider in setting the value of  $\alpha$ : the year-to-year volatility in rail revenues from movements involving the product under consideration. Figure 9 plots the annual operating revenues for the seven Class I railroads operating in the United States from 2002 to 2017.<sup>40</sup> The year-to-year variation in revenues excluding the financial crisis period of 2008 to 2009 provides guidance for selecting the value of  $\alpha$ . Based on these graphs, an annual revenue change of 5 percent is consistent with the year-to-year variation from trend growth in revenues over time for all of the Class I railroads.

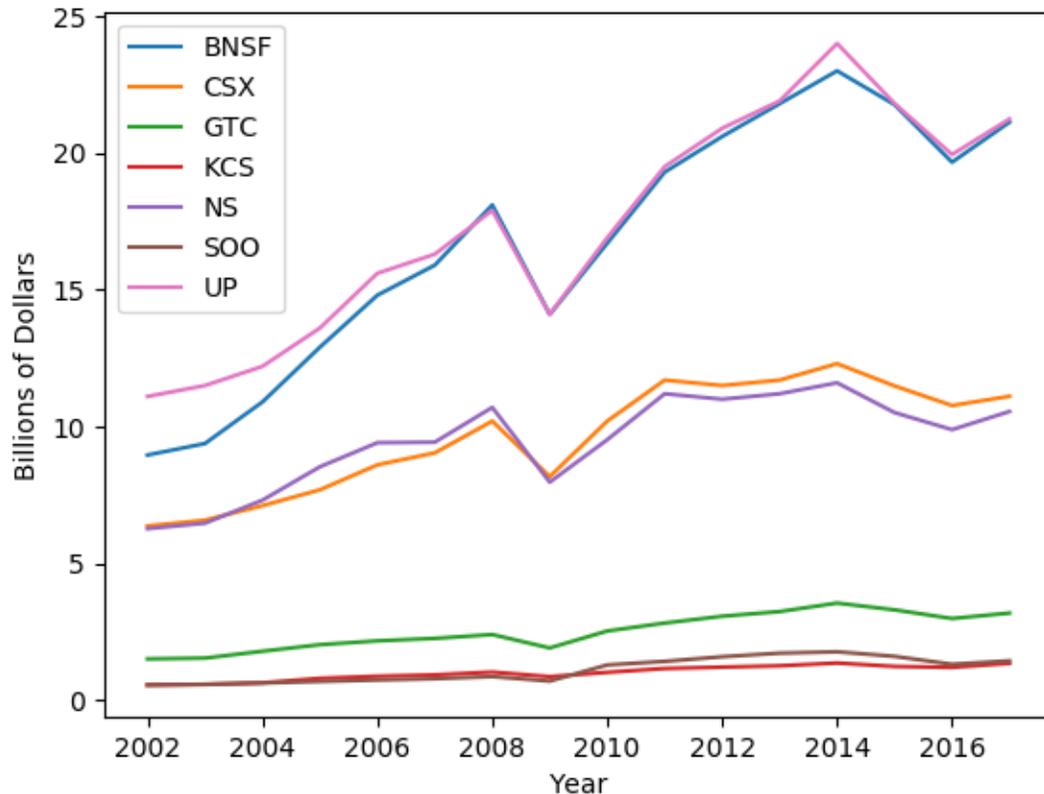

This logic implies that those product categories that typically experience less year-to-year variation in revenues relative to trend should have lower values of  $\alpha$  than those products that experience more year-to-year variation in revenues. Among our four categories of products,

---

<sup>40</sup>BNSF: Burlington Northern and Santa Fe, CSX: CSX Transportation, GTC: Grand Trunk Corporation, KCS: Kansas City Southern Railway, NS: Norfolk Southern Corporation, SOO: SOO Line Corporation, and UP: Union Pacific

we would expect that coal typically experiences the least year-to-year variation in revenues, given that historically coal was used to produce baseload electricity. Petroleum, farm products and chemicals are likely to have higher year-to-year variation in product-level revenues than coal. This logic implies that coal would have a smaller value of  $\alpha$  than the other three products, consistent with our earlier discussion based on the homogeneity of coal shipments.

Figure 9: Annual Operating Revenues for Class I Railroads in the United States from 2002 to 2017

## VII. Concluding Comments

The fact that a growing share of rail shipments are moving at rates that are determined under what the STB determines to be effectively competitive conditions presents an opportunity to use this data to construct a conditional distribution of reasonable prices given shipment characteristics that can be used to determine whether the rate charged for shipment is “excessive.” The computation of this benchmark price can be automatically updated each year given a sample of shipment prices and observable characteristics along with their expansion factors from the annual Carload Waybill Sample. Moreover, this conditional distribution of reasonable prices can be updated to condition on additional observable characteristics that are found to “explain” shipment prices.

This benchmark pricing approach can be used formally and informally in the rate relief process. Formal use would likely require a legislative change, but informal use could involve assessing whether violation of the current standard for an “excessive” price is the result of market dominance by the railroad or group of railroads providing the shipment. The conditional distribution of reasonable prices can also provide input to the process of determining a “reasonable” price for shipment, if the regulatory process finds that a price is “excessive” and the result of market dominance.

## Appendix A

This appendix describes our choice of the kernel function used to compute our estimate of  $\hat{F}(y|X)$  and the procedure we use to estimate the vector of smoothing parameters  $a$ .

For  $K(\cdot)$  we use the Epanechnikov kernel,

$$\begin{aligned} K(x) &= \frac{3}{4}(1 - x^2) \text{ for } |x| < 1 \\ &= 0 \text{ otherwise} \end{aligned}$$

and

$$K_a(X - X_i) = \prod_{j=1}^J \frac{1}{a_j} K\left(\frac{X^j - X_i^j}{a_j}\right)$$

where  $a = (a_1, a_2, \dots, a_J)$ , and  $X^j$  is the  $j^{\text{th}}$  element of  $X$ . Other choices of the kernel function  $K(t)$  produced similar estimates of  $F(t|X)$ . Once the vector  $a$  is selected, our estimate of the  $F(y|X)$  can be computed given a random sample of  $(y_i, X_i)'$  and associated expansion factors  $E F_i$   $i = 1, 2, \dots, N$ . We choose values of  $a$  according to the bootstrap bandwidth selection approach analyzed by Bashtannyk and Hyndman (2001) and originally recommended by Hall et al. (1999).<sup>41</sup>

Our procedure for estimating the bandwidth parameter vector  $a$  for our kernel regression estimator of  $F(y|X)$  first fits a rich polynomial regression

$$y_i = \beta_0 + \sum_{j=1}^J \beta_{j1} X_{ji} + \dots + \beta_{jk} X_{ji}^k + \sigma \epsilon_i$$

where  $\epsilon_i$  are regression errors that are assumed to be independent and identically distributed  $N(0, \sigma^2)$  random variables and  $k$  is determined by Akaike's (1973) Information Criterion. The  $\beta$ 's and  $\sigma$  are estimated from the data. We then form a parametric estimator  $\tilde{F}(y|X)$  from this model based on the assumption that the  $\epsilon_i$  are independent and identical normally distributed random variables. Then we simulate  $l = 1, 2, \dots, L$  bootstrap data sets  $y^{(l)} = \{y_1^{(l)}, \dots, y_n^{(l)}\}$  based on the observations  $X = \{X_1, \dots, X_n\}$  from this parametric model.

We then choose the vector  $a$  to minimize

---

<sup>41</sup>We also employed the cross-validation method set forth in Li and Racine (2008) to compute the bandwidth parameters. However, this method took an order of magnitude longer to run, due to the size of our data, without the resulting parameters being very far from the ones estimated using the method of Hall et

$$\tilde{M}(a; L, \mathbf{y}', \tilde{F}(\cdot|X)) = \frac{1}{L} \sum_{l=1}^L I(a; X, y^{(l)}, \mathbf{y}', \tilde{F}(\cdot|X))$$

where

$$I(a, X, y^{(l)}, \mathbf{y}', \tilde{F}(\cdot|X)) = \frac{\Delta}{N} \sum_{j=1}^Y \sum_{i=1}^N [\hat{F}(y'_j|X_i, a) - \tilde{F}(y'_j|X_i)]^2$$

where  $\mathbf{y}'$  is a vector of  $Y$  evenly spaced values over the sample space of  $y$ , with  $y_{j+1} - y_j = \Delta$ .  $\hat{F}(\cdot|X, a)$  is our non-parametric estimate of the conditional distribution of  $y$  given  $X$  and  $\tilde{F}(y'_j|X_i)$  the parametric estimate of this condition distribution.

Given  $a^*$ , the optimized value of  $a$ , we can compute  $\hat{F}(y|X, a^*)$  for any values of  $y$  and  $X$ . The process of computing the "optimal" value of  $a$  described above can be automated, given a sample of  $(y_i, X'_i)'$  for  $i = 1, 2, \dots, N$ , as each step of the process has well-defined termination rule.
