The dialogue above is from ELIZA, an early natural language processing system that could carry on a limited conversation with a user by imitating the responses of a Rogerian psychotherapist (Weizenbaum, 1966). ELIZA is a surprisingly simple program that uses pattern matching to recognize phrases like “I need X” and translate them into suitable outputs like “What would it mean to you if you got X?”. This simple technique succeeds in this domain because ELIZA doesn’t actually need to know anything to mimic a Rogerian psychotherapist. As Weizenbaum notes, this is one of the few dialogue genres where listeners can act as if they know nothing of the world. ELIZA’s mimicry of human conversation was remarkably successful: many people who interacted with ELIZA came to believe that it really understood them and their problems, many continued to believe in ELIZA’s abilities even after the program’s operation was explained to them (Weizenbaum, 1976), and even today such chatbots are a fun diversion.

Of course modern conversational agents are much more than a diversion; they can answer questions, book flights, or find restaurants, functions for which they rely on a much more sophisticated understanding of the user’s intent, as we will see in Chapter 24. Nonetheless, the simple pattern-based methods that powered ELIZA and other chatbots play a crucial role in natural language processing.

We’ll begin with the most important tool for describing text patterns: the regular expression. Regular expressions can be used to specify strings we might want to extract from a document, from transforming “I need X” in ELIZA above, to defining strings like $199 or $24.99 for extracting tables of prices from a document.

We’ll then turn to a set of tasks collectively called text normalization, in which regular expressions play an important part. Normalizing text means converting it to a more convenient, standard form. For example, most of what we are going to do with language relies on first separating out or tokenizing words from running text, the task of tokenization. English words are often separated from each other by whitespace, but whitespace is not always sufficient. New York and rock ‘n’ roll are sometimes treated as large words despite the fact that they contain spaces, while sometimes we’ll need to separate I’m into the two words I and am. For processing tweets or texts we’ll need to tokenize emoticons like :) or hashtags like #nlp.
Some languages, like Japanese, don’t have spaces between words, so word tokenization becomes more difficult.

Another part of text normalization is lemmatization, the task of determining that two words have the same root, despite their surface differences. For example, the words sang, sung, and sings are forms of the verb sing. The word sing is the common lemma of these words, and a lemmatizer maps from all of these to sing. Lemmatization is essential for processing morphologically complex languages like Arabic. Stemming refers to a simpler version of lemmatization in which we mainly just strip suffixes from the end of the word. Text normalization also includes sentence segmentation: breaking up a text into individual sentences, using cues like periods or exclamation points.

Finally, we’ll need to compare words and other strings. We’ll introduce a metric called edit distance that measures how similar two strings are based on the number of edits (insertions, deletions, substitutions) it takes to change one string into the other. Edit distance is an algorithm with applications throughout language processing, from spelling correction to speech recognition to coreference resolution.

2.1 Regular Expressions

One of the unsung successes in standardization in computer science has been the regular expression (RE), a language for specifying text search strings. This practical language is used in every computer language, word processor, and text processing tools like the Unix tools grep or Emacs. Formally, a regular expression is an algebraic notation for characterizing a set of strings. They are particularly useful for searching in texts, when we have a pattern to search for and a corpus of texts to search through. A regular expression search function will search through the corpus, returning all texts that match the pattern. The corpus can be a single document or a collection. For example, the Unix command-line tool grep takes a regular expression and returns every line of the input document that matches the expression.

A search can be designed to return every match on a line, if there are more than one, or just the first match. In the following examples we generally underline the exact part of the pattern that matches the regular expression and show only the first match. We’ll show regular expressions delimited by slashes but note that slashes are not part of the regular expressions.

Regular expressions come in many variants. We’ll be describing extended regular expressions; different regular expression parsers may only recognize subsets of these, or treat some expressions slightly differently. Using an online regular expression tester is a handy way to test out your expressions and explore these variations.

2.1.1 Basic Regular Expression Patterns

The simplest kind of regular expression is a sequence of simple characters; putting characters in sequence is called concatenation. To search for woodchuck, we type /woodchuck/. The expression /Buttercup/ matches any string containing the substring Buttercup; grep with that expression would return the line I’m called little Buttercup. The search string can consist of a single character (like /!/) or a sequence of characters (like /urg1/).

Regular expressions are case sensitive; lower case /s/ is distinct from upper case /S/ (/s/ matches a lower case s but not an upper case S). This means that
2.1 • Regular Expressions

Figure 2.1 Some simple regex searches.

The pattern `/woodchucks/` will not match the string `Woodchucks`. We can solve this problem with the use of the square braces `[` and `]`. The string of characters inside the braces specifies a disjunction of characters to match. For example, Fig. 2.2 shows that the pattern `/\[wW\]/` matches patterns containing either `w` or `W`.

![Table showing example patterns matched for regular expressions](image)

The regular expression `/\[1234567890\]/` specifies any single digit. While such classes of characters as digits or letters are important building blocks in expressions, they can get awkward (e.g., it’s inconvenient to specify

```
/\[ABCDEFGHIJKLMNOPQRSTUVWXYZ\]/
```

to mean “any capital letter”). In cases where there is a well-defined sequence associated with a set of characters, the brackets can be used with the dash (`-`) to specify any one character in a range. The pattern `/\[2-5\]/` specifies any one of the characters 2, 3, 4, or 5. The pattern `/\[b-g\]/` specifies one of the characters `b`, `c`, `d`, `e`, `f`, or `g`. Some other examples are shown in Fig. 2.3.

![Table showing example patterns matched for regular expressions](image)

The square braces can also be used to specify what a single character cannot be, by use of the caret `^`. If the caret `^` is the first symbol after the open square brace `[`, the resulting pattern is negated. For example, the pattern `/\[^a\]/` matches any single character (including special characters) except `a`. This is only true when the caret is the first symbol after the open square brace. If it occurs anywhere else, it usually stands for a caret; Fig. 2.4 shows some examples.

![Table showing example patterns matched for regular expressions](image)

How can we talk about optional elements, like an optional `s` in `woodchuck` and `woodchucks`? We can’t use the square brackets, because while they allow us to say
Regular Expressions, Text Normalization, Edit Distance

Chapter 2

“s or S”, they don’t allow us to say “s or nothing”. For this we use the question mark /?/, which means “the preceding character or nothing”, as shown in Fig. 2.5.

<table>

</tr>
<tr>
<td>/colou?r/</td>
<td>color or colour</td>
<td>“color”</td>
</tr>
</tbody>
</table>

Figure 2.5 The question mark ? marks optionality of the previous expression.

We can think of the question mark as meaning “zero or one instances of the previous character”. That is, it’s a way of specifying how many of something that we want, something that is very important in regular expressions. For example, consider the language of certain sheep, which consists of strings that look like the following:

baa!
baaa!
baaaa!
baaaaa!
...

This language consists of strings with a b, followed by at least two a’s, followed by an exclamation point. The set of operators that allows us to say things like “some number of a’s” are based on the asterisk or *, commonly called the Kleene * (generally pronounced “cleany star”). The Kleene star means “zero or more occurrences of the immediately previous character or regular expression”. So /a*/ means “any string of zero or more a’s”. This will match a or aaaa, but it will also match Off Minor since the string Off Minor has zero a’s. So the regular expression for matching one or more a is /aa*/. meaning one a followed by zero or more a’s. More complex patterns can also be repeated. So /[ab]*/ means “zero or more a’s or b’s” (not “zero or more right square braces”). This will match strings like aaaa or ababab or bbbb.

For specifying multiple digits (useful for finding prices) we can extend /[0-9]/, the regular expression for a single digit. An integer (a string of digits) is thus /([0-9])*/. (Why isn’t it just /([0-9])*/?)

Sometimes it’s annoying to have to write the regular expression for digits twice, so there is a shorter way to specify “at least one” of some character. This is the Kleene +, which means “one or more occurrences of the immediately preceding character or regular expression”. Thus, the expression /([0-9])+/ is the normal way to specify “a sequence of digits”. There are thus two ways to specify the sheep language: /bbaa*/ or /baa+/. One very important special character is the period (./), a wildcard expression that matches any single character (except a carriage return), as shown in Fig. 2.6.

<table>
<thead>
<tr>
<th>RE</th>
<th>Match</th>
<th>Example Matches</th>
</tr>
</thead>
<tbody>
<tr>
<td>/beg.n/</td>
<td>any character between beg and n</td>
<td>begin, beg’n, begn</td>
</tr>
</tbody>
</table>

Figure 2.6 The use of the period . to specify any character.

The wildcard is often used together with the Kleene star to mean “any string of characters”. For example, suppose we want to find any line in which a particular word, for example, aardvark, appears twice. We can specify this with the regular expression /aardvark.*aardvark/.

Anchors are special characters that anchor regular expressions to particular places
in a string. The most common anchors are the caret ^ and the dollar sign $. The caret ^ matches the start of a line. The pattern /\^The/ matches the word The only at the start of a line. Thus, the caret ^ has three uses: to match the start of a line, to indicate a negation inside of square brackets, and just to mean a caret. (What are the contexts that allow grep or Python to know which function a given caret is supposed to have?) The dollar sign $ matches the end of a line. So the pattern ^\$ is a useful pattern for matching a space at the end of a line, and /\^The .\$/ matches a line that contains only the phrase The dog. (We have to use the backslash here since we want the . to mean “period” and not the wildcard.)

<table>

</tr>
<tr>
<td>\b</td>
<td>word boundary</td>
</tr>
<tr>
<td>\B</td>
<td>non-word boundary</td>
</tr>
</tbody>
</table>

Figure 2.7 Anchors in regular expressions.

There are also two other anchors: \b matches a word boundary, and \B matches a non-boundary. Thus, /\bthe\b/ matches the word the but not the word other. More technically, a “word” for the purposes of a regular expression is defined as any sequence of digits, underscores, or letters; this is based on the definition of “words” in programming languages. For example, /\b99\b/ will match the string 99 in There are 99 bottles of beer on the wall (because 99 follows a space) but not 99 in There are 299 bottles of beer on the wall (since 99 follows a number). But it will match 99 in $99 (since 99 follows a dollar sign ($), which is not a digit, underscore, or letter).

2.1.2 Disjunction, Grouping, and Precedence

Suppose we need to search for texts about pets; perhaps we are particularly interested in cats and dogs. In such a case, we might want to search for either the string cat or the string dog. Since we can’t use the square brackets to search for “cat or dog” (why can’t we say /\[catdog\]/?), we need a new operator, the disjunction operator, also called the pipe symbol |. The pattern /cat|dog/ matches either the string cat or the string dog.

Sometimes we need to use this disjunction operator in the midst of a larger sequence. For example, suppose I want to search for information about pet fish for my cousin David. How can I specify both guppy and guppies? We cannot simply say /guppy|ies/, because that would match only the strings guppy and ies. This is because sequences like guppy take precedence over the disjunction operator |. To make the disjunction operator apply only to a specific pattern, we need to use the parenthesis operators ( and ). Enclosing a pattern in parentheses makes it act like a single character for the purposes of neighboring operators like the pipe | and the Kleene*. So the pattern /gupp(y|ies)/ would specify that we meant the disjunction only to apply to the suffixes y and ies.

The parenthesis operator ( is also useful when we are using counters like the Kleene*. Unlike the | operator, the Kleene* operator applies by default only to a single character, not to a whole sequence. Suppose we want to match repeated instances of a string. Perhaps we have a line that has column labels of the form Column 1 Column 2 Column 3. The expression /Column\_[0-9]+\_\*/ will not match any number of columns; instead, it will match a single column followed by
any number of spaces! The star here applies only to the space \( \cdot \) that precedes it, not to the whole sequence. With the parentheses, we could write the expression
\[
/(\text{Column}_[0-9]+[^*]*/
\]
to match the word \textit{Column}, followed by a number and optional spaces, the whole pattern repeated zero or more times.

This idea that one operator may take precedence over another, requiring us to sometimes use parentheses to specify what we mean, is formalized by the \textbf{operator precedence hierarchy} for regular expressions. The following table gives the order of \textit{RE} operator precedence, from highest precedence to lowest precedence.

<table>
<thead>
<tr>
<th>Operator</th>
<th>Precedence</th>
</tr>
</thead>
<tbody>
<tr>
<td>Parenthesis</td>
<td>()</td>
</tr>
<tr>
<td>Counters</td>
<td>*, +, ?, {}</td>
</tr>
<tr>
<td>Sequences and anchors</td>
<td>the ^my end$</td>
</tr>
<tr>
<td>Disjunction</td>
<td></td>
</tr>
</tbody>
</table>

Thus, because counters have a higher precedence than sequences, \texttt{/the*/} matches \texttt{theeeee} but not \texttt{thethe}. Because sequences have a higher precedence than disjunction, \texttt{/the|any/} matches \texttt{the or any} but not \texttt{than or thany}.

Patterns can be ambiguous in another way. Consider the expression \texttt{/[^a-z]*/} when matching against the text \texttt{once upon a time}. Since \texttt{/[^a-z]*/} matches zero or more letters, this expression could match nothing, or just the first letter \texttt{o}, \texttt{on}, \texttt{onc}, or \texttt{once}. In these cases regular expressions always match the largest string they can; we say that patterns are \textbf{greedy}, expanding to cover as much of a string as they can.

There are, however, ways to enforce \textbf{non-greedy} matching, using another meaning of the \texttt{?} qualifier. The operator \texttt{*?} is a Kleene star that matches as little text as possible. The operator \texttt{+?} is a Kleene plus that matches as little text as possible.

### 2.1.3 A Simple Example

Suppose we wanted to write a \textit{RE} to find cases of the English article \textit{the}. A simple (but incorrect) pattern might be:

\[
/\text{the}/
\]

One problem is that this pattern will miss the word when it begins a sentence and hence is capitalized (i.e., \textit{The}). This might lead us to the following pattern:

\[
/[tT]he/\]

But we will still incorrectly return texts with \textit{the} embedded in other words (e.g., \textit{other} or \textit{theology}). So we need to specify that we want instances with a word boundary on both sides:

\[
/\b[tT]he\b/
\]

Suppose we wanted to do this without the use of \texttt{\b/}. We might want this since \texttt{\b/} won’t treat underscores and numbers as word boundaries; but we might want to find \textit{the} in some context where it might also have underlines or numbers nearby (\textit{the}_ or \textit{the25}). We need to specify that we want instances in which there are no alphabetic letters on either side of the \textit{the}:

\[
/[\^a-zA-Z][tT]he[^a-zA-Z]/
\]

But there is still one more problem with this pattern: it won’t find the word \textit{the} when it begins a line. This is because the regular expression \texttt{[^a-zA-ZA-Z]}, which
we used to avoid embedded instances of the, implies that there must be some single (although non-alphabetic) character before the the. We can avoid this by specifying that before the the we require either the beginning-of-line or a non-alphabetic character, and the same at the end of the line:

```
/(\^|[^a-zA-Z]) the([^a-zA-Z]|$)/
```

The process we just went through was based on fixing two kinds of errors: **false positives**, strings that we incorrectly matched like other or there, and **false negatives**, strings that we incorrectly missed, like The. Addressing these two kinds of errors comes up again and again in implementing speech and language processing systems. Reducing the overall error rate for an application thus involves two antagonistic efforts:

- Increasing **precision** (minimizing false positives)
- Increasing **recall** (minimizing false negatives)

We’ll come back to precision and recall with more precise definitions in Chapter 4.

### 2.1.4 More Operators

Figure 2.8 shows some aliases for common ranges, which can be used mainly to save typing. Besides the Kleene * and Kleene + we can also use explicit numbers as counters, by enclosing them in curly brackets. The regular expression /{3}/ means “exactly 3 occurrences of the previous character or expression”. So /a\.{24}z/ will match a followed by 24 dots followed by z (but not a followed by 23 or 25 dots followed by a z).

<td>[^\s]</td>
<td>Non-whitespace</td>
<td></td>
</tr>
</tbody>
</table>

**Figure 2.8** Aliases for common sets of characters.

A range of numbers can also be specified. So /{n,m}/ specifies from n to m occurrences of the previous char or expression, and /{n,}/ means at least n occurrences of the previous expression. REs for counting are summarized in Fig. 2.9.

### 2.1.5 A More Complex Example

Let’s try out a more significant example of the power of REs. Suppose we want to build an application to help a user buy a computer on the Web. The user might want “any machine with at least 6 GHz and 500 GB of disk space for less than $1000”. To do this kind of retrieval, we first need to be able to look for expressions like 6 GHz or 500 GB or Mac or $999.99. In the rest of this section we’ll work out some simple regular expressions for this task.

First, let’s complete our regular expression for prices. Here’s a regular expression for a dollar sign followed by a string of digits:

```
/\$[0-9]+/
```

Note that the $ character has a different function here than the end-of-line function we discussed earlier. Most regular expression parsers are smart enough to realize that $ here doesn’t mean end-of-line. (As a thought experiment, think about how regex parsers might figure out the function of $ from the context.)

Now we just need to deal with fractions of dollars. We’ll add a decimal point and two digits afterwards:

```
/\$[0-9]+\.[0-9][0-9]/
```

This pattern only allows $199.99 but not $199. We need to make the cents optional and to make sure we’re at a word boundary:

```
/(^|\W)\$[0-9]+(\.[0-9][0-9])?\b/
```

One last catch! This pattern allows prices like $199999.99 which would be far too expensive! We need to limit the dollars:

```
/(^|\W)\$[0-9]{0,3}(\.[0-9][0-9])?\b/
```

How about disk space? We’ll need to allow for optional fractions again (5.5 GB); note the use of ? for making the final s optional, and the of /\*/ to mean “zero or more spaces” since there might always be extra spaces lying around:

```
/\b\([0-9]+(\.[0-9]+)?\*\((GB([Gg])igabytes?)\)/
```

Modifying this regular expression so that it only matches more than 500 GB is left as an exercise for the reader.
2.1.6 Substitution, Capture Groups, and ELIZA

An important use of regular expressions is in substitutions. For example, the substitution operator `s/regexp1/pattern/` used in Python and in Unix commands like `vim` or `sed` allows a string characterized by a regular expression to be replaced by another string:

`s/colour/color/`

It is often useful to be able to refer to a particular subpart of the string matching the first pattern. For example, suppose we wanted to put angle brackets around all integers in a text, for example, changing the 35 boxes to the `<35>` boxes. We’d like a way to refer to the integer we’ve found so that we can easily add the brackets. To do this, we put parentheses ( and ) around the first pattern and use the number operator \1 in the second pattern to refer back. Here’s how it looks:

`s/([0-9]+)/<\1>/`

The parenthesis and number operators can also specify that a certain string or expression must occur twice in the text. For example, suppose we are looking for the pattern “the Xer they were, the Xer they will be”, where we want to constrain the two X’s to be the same string. We do this by surrounding the first X with the parenthesis operator, and replacing the second X with the number operator \1, as follows:

`/the (.*)er they (.*), the \1er the \2/`

Here the \1 will be replaced by whatever string matched the first item in parentheses. So this will match the bigger they were, the bigger they will be but not the bigger they were, the faster they will be.

This use of parentheses to store a pattern in memory is called a capture group. Every time a capture group is used (i.e., parentheses surround a pattern), the resulting match is stored in a numbered register. If you match two different sets of parentheses, \2 means whatever matched the second capture group. Thus

`/the (.*)er they (.*), the \1er we \2/`

will match the faster they ran, the faster we ran but not the faster they ran, the faster we ate. Similarly, the third capture group is stored in \3, the fourth is \4, and so on.

Parentheses thus have a double function in regular expressions; they are used to group terms for specifying the order in which operators should apply, and they are used to capture something in a register. Occasionally we might want to use parentheses for grouping, but don’t want to capture the resulting pattern in a register. In that case we use a non-capturing group, which is specified by putting the commands `?` after the open paren, in the form `(?: pattern )`

`/(?:(?:some|a few) (people|cats) like some \1/)`

will match some cats like some cats but not some cats like some a few.

Substitutions and capture groups are very useful in implementing simple chatbots like ELIZA (Weizenbaum, 1966). Recall that ELIZA simulates a Rogerian psychologist by carrying on conversations like the following:
User 1: Men are all alike.
ELIZA 1: IN WHAT WAY
User 2: They’re always bugging us about something or other.
ELIZA 2: CAN YOU THINK OF A SPECIFIC EXAMPLE
User 3: Well, my boyfriend made me come here.
ELIZA 3: YOUR BOYFRIEND MADE YOU COME HERE
User 4: He says I’m depressed much of the time.
ELIZA 4: I AM SORRY TO HEAR YOU ARE DEPRESSED

ELIZA works by having a series or cascade of regular expression substitutions each of which matches and changes some part of the input lines. Input lines are first uppercased. The first substitutions then change all instances of MY to YOUR, and I’M to YOU ARE, and so on. The next set of substitutions matches and replaces other patterns in the input. Here are some examples:

```
s/.*/ I'M (.depressed|sad) ./ I AM SORRY TO HEAR YOU ARE \1/
s/.*/ I AM (.depressed|sad) ./ WHY DO YOU THINK YOU ARE \1/
s/.*/ all ./ IN WHAT WAY/
s/.*/ always ./ CAN YOU THINK OF A SPECIFIC EXAMPLE/
```

Since multiple substitutions can apply to a given input, substitutions are assigned a rank and applied in order. Creating patterns is the topic of Exercise 2.3, and we return to the details of the ELIZA architecture in Chapter 24.

### 2.1.7 Lookahead Assertions

Finally, there will be times when we need to predict the future: look ahead in the text to see if some pattern matches, but not advance the match cursor, so that we can then deal with the pattern if it occurs.

These lookahead assertions make use of the (?= pattern) syntax that we saw in the previous section for non-capture groups. The operator (?= pattern) is true if pattern occurs, but is zero-width, i.e. the match pointer doesn’t advance. The operator (?! pattern) only returns true if a pattern does not match, but again is zero-width and doesn’t advance the cursor. Negative lookahead is commonly used when we are parsing some complex pattern but want to rule out a special case. For example suppose we want to match, at the beginning of a line, any single word that doesn’t start with “Volcano”. We can use negative lookahead to do this:

```
/ˆ(?!Volcano)[A-Za-z]+/
```

### 2.2 Words

Before we talk about processing words, we need to decide what counts as a word. Let’s start by looking at one particular corpus (plural corpora), a computer-readable collection of text or speech. For example the Brown corpus is a million-word collection of samples from 500 written English texts from different genres (newspaper, fiction, non-fiction, academic, etc.), assembled at Brown University in 1963–64 (Kučera and Francis, 1967). How many words are in the following Brown sentence?

He stepped out into the hall, was delighted to encounter a water brother.
This sentence has 13 words if we don’t count punctuation marks as words, 15 if we count punctuation. Whether we treat period ("."), comma (","), and so on as words depends on the task. Punctuation is critical for finding boundaries of things (commas, periods, colons) and for identifying some aspects of meaning (question marks, exclamation marks, quotation marks). For some tasks, like part-of-speech tagging or parsing or speech synthesis, we sometimes treat punctuation marks as if they were separate words.

The Switchboard corpus of American English telephone conversations between strangers was collected in the early 1990s; it contains 2430 conversations averaging 6 minutes each, totaling 240 hours of speech and about 3 million words (Godfrey et al., 1992). Such corpora of spoken language don’t have punctuation but do introduce other complications with regard to defining words. Let’s look at one utterance from Switchboard; an utterance is the spoken correlate of a sentence:

I do uh main- mainly business data processing

This utterance has two kinds of disfluencies. The broken-off word main- is called a fragment. Words like uh and um are called fillers or filled pauses. Should we consider these to be words? Again, it depends on the application. If we are building a speech transcription system, we might want to eventually strip out the disfluencies.

But we also sometimes keep disfluencies around. Disfluencies like uh or um are actually helpful in speech recognition in predicting the upcoming word, because they may signal that the speaker is restarting the clause or idea, and so for speech recognition they are treated as regular words. Because people use different disfluencies they can also be a cue to speaker identification. In fact Clark and Fox Tree (2002) showed that uh and um have different meanings. What do you think they are?

Are capitalized tokens like They and uncapitalized tokens like they the same word? These are lumped together in some tasks (speech recognition), while for part-of-speech or named-entity tagging, capitalization is a useful feature and is retained.

How about inflected forms like cats versus cat? These two words have the same lemma cat but are different wordforms. A lemma is a set of lexical forms having the same stem, the same major part-of-speech, and the same word sense. The wordform is the full inflected or derived form of the word. For morphologically complex languages like Arabic, we often need to deal with lemmatization. For many tasks in English, however, wordforms are sufficient.

How many words are there in English? To answer this question we need to distinguish two ways of talking about words. Types are the number of distinct words in a corpus; if the set of words in the vocabulary is \( V \), the number of types is the vocabulary size \( |V| \). Tokens are the total number \( N \) of running words. If we ignore punctuation, the following Brown sentence has 16 tokens and 14 types:

They picnicked by the pool, then lay back on the grass and looked at the stars.

When we speak about the number of words in the language, we are generally referring to word types.

Fig. 2.11 shows the rough numbers of types and tokens computed from some popular English corpora. The larger the corpora we look at, the more word types we find, and in fact this relationship between the number of types \( |V| \) and number of tokens \( N \) is called Herdan’s Law (Herdan, 1960) or Heaps’ Law (Heaps, 1978) after its discoverers (in linguistics and information retrieval respectively). It is shown in Eq. 2.1, where \( k \) and \( \beta \) are positive constants, and \( 0 < \beta < 1 \).

\[
|V| = kN^\beta
\]
Corpus & Tokens = N & Types = |V|

<table>
<thead>

<td>1 trillion</td>
<td>13 million</td>
</tr>
</tbody>
</table>

**Figure 2.11** Rough numbers of types and tokens for some English language corpora. The largest, the Google n-grams corpus, contains 13 million types, but this count only includes types appearing 40 or more times, so the true number would be much larger.

The value of $\beta$ depends on the corpus size and the genre, but at least for the large corpora in Fig. 2.11, $\beta$ ranges from .67 to .75. Roughly then we can say that the vocabulary size for a text goes up significantly faster than the square root of its length in words.

Another measure of the number of words in the language is the number of lemmas instead of wordform types. Dictionaries can help in giving lemma counts; dictionary entries or boldface forms are a very rough upper bound on the number of lemmas (since some lemmas have multiple boldface forms). The 1989 edition of the Oxford English Dictionary had 615,000 entries.

### 2.3 Corpora

Words don’t appear out of nowhere. Any particular piece of text that we study is produced by one or more specific speakers or writers, in a specific dialect of a specific language, at a specific time, in a specific place, for a specific function.

Perhaps the most important dimension of variation is the language. NLP algorithms are most useful when they apply across many languages. The world has 7097 languages at the time of this writing, according to the online Ethnologue catalog (Simons and Fennig, 2018). It is important to test algorithms on more than one language, and particularly on languages with different properties; by contrast there is an unfortunate current tendency for NLP algorithms to be developed or tested just on English (Bender, 2019). Even when algorithms are developed beyond English, they tend to be developed for the official languages of large industrialized nations (Chinese, Spanish, Japanese, German etc.), but we don’t want to limit tools to just these few languages. Furthermore, most languages also have multiple varieties, often spoken in different regions or by different social groups. Thus, for example, if we’re processing text that uses features of African American English (AAE) or African American Vernacular English (AAVE)—the variations of English used by millions of people in African American communities (King 2020)—we must use NLP tools that function with features of those varieties. Twitter posts might use features often used by speakers of African American English, such as constructions like *iont* (*I don’t* in Mainstream American English (MAE)), or *talmbout* corresponding to MAE *talking about*, both examples that influence word segmentation (Blodgett et al. 2016, Jones 2015).

It’s also quite common for speakers or writers to use multiple languages in a single communicative act, a phenomenon called **code switching**. Code switching is enormously common across the world; here are examples showing Spanish and (transliterated) Hindi code switching with English (Solorio et al. 2014, Jurgens et al. 2017):
2.4 Text Normalization

Before almost any natural language processing of a text, the text has to be normalized. At least three tasks are commonly applied as part of any normalization process:

1. Tokenizing (segmenting) words
2. Normalizing word formats
3. Segmenting sentences

In the next sections we walk through each of these tasks.
2.4.1 Unix Tools for Crude Tokenization and Normalization

Let's begin with an easy, if somewhat naive version of word tokenization and normalization (and frequency computation) that can be accomplished for English solely in a single UNIX command-line, inspired by Church (1994). We'll make use of some Unix commands: tr, used to systematically change particular characters in the input; sort, which sorts input lines in alphabetical order; and uniq, which collapses and counts adjacent identical lines.

For example let's begin with the ‘complete words’ of Shakespeare in one file, sh.txt. We can use tr to tokenize the words by changing every sequence of non-alphabetic characters to a newline ('A-Za-z' means alphabetic, the -c option complements to non-alphabet, and the -s option squeezes all sequences into a single character):

```
tr -sc 'A-Za-z' \n < sh.txt
```

The output of this command will be:

```
THE
SONNETS
by
William
Shakespeare
From
fairest
creatures
We
...
```

Now that there is one word per line, we can sort the lines, and pass them to uniq -c which will collapse and count them:

```
tr -sc 'A-Za-z' \n < sh.txt | sort | uniq -c
```

with the following output:

```
1945 A
72 AARON
19 ABBESS
25 Aaron
6 Abate
1 Abates
5 Abbess
6 Abbey
3 Abbot
...
```

Alternatively, we can collapse all the upper case to lower case:

```
tr -sc 'A-Za-z' \n < sh.txt | tr A-Z a-z | sort | uniq -c
```

whose output is

```
14725 a
97 aaron
1 abaissiez
10 abandon
2 abandoned
```
Now we can sort again to find the frequent words. The `-n` option to `sort` means to sort numerically rather than alphabetically, and the `-r` option means to sort in reverse order (highest-to-lowest):

```
tr -sc 'A-Za-z' '
' < sh.txt | tr A-Z a-z | sort | uniq -c | sort -n -r
```

The results show that the most frequent words in Shakespeare, as in any other corpus, are the short **function words** like articles, pronouns, prepositions:

```
27378 the
26084 and
22538 i
19771 to
17481 of
14725 a
13826 you
12489 my
11318 that
11112 in
... 
```

Unix tools of this sort can be very handy in building quick word count statistics for any corpus.

### 2.4.2 Word Tokenization

The simple UNIX tools above were fine for getting rough word statistics but more sophisticated algorithms are generally necessary for **tokenization**, the task of segmenting running text into words.

While the Unix command sequence just removed all the numbers and punctuation, for most NLP applications we’ll need to keep these in our tokenization. We often want to break off punctuation as a separate token; commas are a useful piece of information for parsers, periods help indicate sentence boundaries. But we’ll often want to keep the punctuation that occurs word internally, in examples like `m.p.h.` or `AT&T`, and `cap’n`. Special characters and numbers will need to be kept in prices ($45.55) and dates (01/02/06); we don’t want to segment that price into separate tokens of “45” and “55”. And there are URLs (http://www.stanford.edu), Twitter hashtags (`#nlproc`), or email addresses (`someone@cs.colorado.edu`).

Number expressions introduce other complications as well; while commas normally appear at word boundaries, commas are used inside numbers in English, every three digits: **555, 500, 50**. Languages, and hence tokenization requirements, differ on this; many continental European languages like Spanish, French, and German, by contrast, use a comma to mark the decimal point, and spaces (or sometimes periods) where English puts commas, for example, **555, 500, 50**.

A tokenizer can also be used to expand **clitic** contractions that are marked by apostrophes, for example, converting `what’re` to the two tokens `what are`, and `we’re to we are`. A clitic is a part of a word that can’t stand on its own, and can only
occur when it is attached to another word. Some such contractions occur in other alphabetic languages, including articles and pronouns in French ("j'ai, l'homme").

Depending on the application, tokenization algorithms may also tokenize multiword expressions like New York or rock 'n' roll as a single token, which requires a multiword expression dictionary of some sort. Tokenization is thus intimately tied up with named entity recognition, the task of detecting names, dates, and organizations (Chapter 8).

One commonly used tokenization standard is known as the Penn Treebank tokenization standard, used for the parsed corpora (treebanks) released by the Linguistic Data Consortium (LDC), the source of many useful datasets. This standard separates out clitics (doesn't becomes does plus n't), keeps hyphenated words together, and separates out all punctuation (to save space we're showing visible spaces . between tokens, although newlines is a more common output):

Input: "The San Francisco-based restaurant," they said, "doesn't charge $10".

Output: ",The,San,Francisco-based,restaurant,",,they,said,,",,doesn,,t,charge,$,10,."

In practice, since tokenization needs to be run before any other language processing, it needs to be very fast. The standard method for tokenization is therefore to use deterministic algorithms based on regular expressions compiled into very efficient finite state automata. For example, Fig. 2.12 shows an example of a basic regular expression that can be used to tokenize with the nltk.regexp_tokenize function of the Python-based Natural Language Toolkit (NLTK) (Bird et al. 2009; http://www.nltk.org).

```python
>>> text = 'That U.S.A. poster-print costs $12.40...'
>>> pattern = r'''(?x) # set flag to allow verbose regexps
... ([A-Z]\.|\.)+ # abbreviations, e.g. U.S.A.
... | \w+(\-\w+)* # words with optional internal hyphens
... | $\d+(\.\d+)?%? # currency and percentages, e.g. $12.40, 82%
... | \.|\.|\.| # ellipsis
... | [\[\],;:'\"\-_,.] # these are separate tokens; includes ], [
... ...
>>> nltk.regexp_tokenize(text, pattern)
['That', 'U.S.A.', 'poster-print', 'costs', '$12.40', '...']
```

Figure 2.12 A Python trace of regular expression tokenization in the NLTK Python-based natural language processing toolkit (Bird et al., 2009), commented for readability; the (?x) verbose flag tells Python to strip comments and whitespace. Figure from Chapter 3 of Bird et al. (2009).

Carefully designed deterministic algorithms can deal with the ambiguities that arise, such as the fact that the apostrophe needs to be tokenized differently when used as a genitive marker (as in the book’s cover), a quotative as in ‘The other class’, she said, or in clitics like they're.

Word tokenization is more complex in languages like written Chinese, Japanese, and Thai, which do not use spaces to mark potential word-boundaries. In Chinese, for example, words are composed of characters (called hanzi in Chinese). Each character generally represents a single unit of meaning (called a morpheme) and is pronounceable as a single syllable. Words are about 2.4 characters long on average.
But deciding what counts as a word in Chinese is complex. For example, consider the following sentence:

(2.4) 姚明进入总决赛
    “Yao Ming reaches the finals”

As Chen et al. (2017) point out, this could be treated as 3 words (‘Chinese Treebank’ segmentation):

(2.5) 姚明进入总决赛
    YaoMing reaches finals

or as 5 words (‘Peking University’ segmentation):

(2.6) 姚明进入总决赛
    Yao Ming reaches overall finals

Finally, it is possible in Chinese simply to ignore words altogether and use characters as the basic elements, treating the sentence as a series of 7 characters:

(2.7) 姚明进入总决赛
    Yao Ming enter enter overall decision game

In fact, for most Chinese NLP tasks it turns out to work better to take characters rather than words as input, since characters are at a reasonable semantic level for most applications, and since most word standards, by contrast, result in a huge vocabulary with large numbers of very rare words (Li et al., 2019).

However, for Japanese and Thai the character is too small a unit, and so algorithms for word segmentation are required. These can also be useful for Chinese in the rare situations where word rather than character boundaries are required. The standard segmentation algorithms for these languages use neural sequence models trained via supervised machine learning on hand-segmented training sets; we’ll introduce sequence models in Chapter 8 and Chapter 9.

### 2.4.3 Byte-Pair Encoding for Tokenization

There is a third option to tokenizing text. Instead of defining tokens as words (whether delimited by spaces or more complex algorithms), or as characters (as in Chinese), we can use our data to automatically tell us what the tokens should be. This is especially useful in dealing with unknown words, an important problem in language processing. As we will see in the next chapter, NLP algorithms often learn some facts about language from one corpus (a training corpus) and then use these facts to make decisions about a separate test corpus and its language. Thus if our training corpus contains, say the words low, new, newer, but not lower, then if the word lower appears in our test corpus, our system will not know what to do with it.

To deal with this unknown word problem, modern tokenizers often automatically induce sets of tokens that include tokens smaller than words, called subwords. Subwords can be arbitrary substrings, or they can be meaning-bearing units like the morphemes -est or -er. (A morpheme is the smallest meaning-bearing unit of a language; for example the word unlikeliest has the morphemes un-, likely, and -est.) In modern tokenization schemes, most tokens are words, but some tokens are frequently occurring morphemes or other subwords like -er. Every unseen word like lower can thus be represented by some sequence of known subword units, such as low and er, or even as a sequence of individual letters if necessary.

Most tokenization schemes have two parts: a token learner, and a token segmenter. The token learner takes a raw training corpus (sometimes roughly pre-separated into words, for example by whitespace) and induces a vocabulary, a set
of tokens. The token segmenter takes a raw test sentence and segments it into the
tokens in the vocabulary. Three algorithms are widely used: byte-pair encoding
(Sennrich et al., 2016), unigram language modeling (Kudo, 2018), and WordPiece
(Schuster and Nakajima, 2012); there is also a SentencePiece library that includes
implementations of the first two of the three (Kudo and Richardson, 2018).

In this section we introduce the simplest of the three, the byte-pair encoding or
BPE algorithm (Sennrich et al., 2016); see Fig. 2.13. The BPE token learner begins
with a vocabulary that is just the set of all individual characters. It then examines the
training corpus, chooses the two symbols that are most frequently adjacent (say ‘A’,
‘B’), adds a new merged symbol ‘AB’ to the vocabulary, and replaces every adjacent
‘A’ ‘B’ in the corpus with the new ‘AB’. It continues to count and merge, creating
new longer and longer character strings, until k merges have been done creating
k novel tokens; k is thus a parameter of the algorithm. The resulting vocabulary
consists of the original set of characters plus k new symbols.

The algorithm is usually run inside words (not merging across word boundaries),
so the input corpus is first white-space-separated to give a set of strings, each corre-
sponding to the characters of a word, plus a special end-of-word symbol __ and its
counts. Let’s see its operation on the following tiny input corpus of 18 word tokens
with counts for each word (the word low appears 5 times, the word newer 6 times,
and so on), which would have a starting vocabulary of 11 letters:

<table>
<thead>
<tr>
<th>corpus</th>
<th>vocabulary</th>
</tr>
</thead>
<tbody>
<tr>
<td>5 low__</td>
<td>__, d, e, i, l, n, o, r, s, t, w</td>
</tr>
<tr>
<td>2 lowest_</td>
<td></td>
</tr>
<tr>
<td>6 newer__</td>
<td></td>
</tr>
<tr>
<td>3 wider__</td>
<td></td>
</tr>
<tr>
<td>2 new__</td>
<td></td>
</tr>
</tbody>
</table>

The BPE algorithm first counts all pairs of adjacent symbols: the most frequent
is the pair er because it occurs in newer (frequency of 6) and wider (frequency of
3) for a total of 9 occurrences¹. We then merge these symbols, treating er as one
symbol, and count again:

<table>
<thead>
<tr>
<th>corpus</th>
<th>vocabulary</th>
</tr>
</thead>
<tbody>
<tr>
<td>5 low__</td>
<td>__, d, e, i, l, n, o, r, s, t, w, er</td>
</tr>
<tr>
<td>2 lowest_</td>
<td></td>
</tr>
<tr>
<td>6 newer__</td>
<td></td>
</tr>
<tr>
<td>3 wider__</td>
<td></td>
</tr>
<tr>
<td>2 new__</td>
<td></td>
</tr>
</tbody>
</table>

Now the most frequent pair is er __, which we merge; our system has learned
that there should be a token for word-final er, represented as er__:

<table>
<thead>
<tr>
<th>corpus</th>
<th>vocabulary</th>
</tr>
</thead>
<tbody>
<tr>
<td>5 low__</td>
<td><strong>, d, e, i, l, n, o, r, s, t, w, er, er</strong></td>
</tr>
<tr>
<td>2 lowest_</td>
<td></td>
</tr>
<tr>
<td>6 newer__</td>
<td></td>
</tr>
<tr>
<td>3 wider__</td>
<td></td>
</tr>
<tr>
<td>2 new__</td>
<td></td>
</tr>
</tbody>
</table>

Next n e (total count of 8) get merged to ne:

---
¹ Note that there can be ties; we could have instead chosen to merge r__ first, since that also has a
frequency of 9.
function BYTE-PAIR ENCODING((strings C, number of merges k)) returns vocab V

V ← all unique characters in C  \hspace{5pt} \# initial set of tokens is characters

for i = 1 to k do  \hspace{5pt} \# merge tokens til k times
  t_L, t_R ← Most frequent pair of adjacent tokens in C
  t_{new} ← t_L + t_R  \hspace{5pt} \# make new token by concatenating
  V ← V + t_{new}  \hspace{5pt} \# update the vocabulary
  Replace each occurrence of t_L, t_R in C with t_{new}  \hspace{5pt} \# and update the corpus

return V

Figure 2.13 The token learner part of the BPE algorithm for taking a corpus broken up into individual characters or bytes, and learning a vocabulary by iteratively merging tokens. Figure adapted from Bostrom and Durrett (2020).

Once we’ve learned our vocabulary, the token parser is used to tokenize a test sentence. The token parser just runs on the test data the merges we have learned from the training data, greedily, in the order we learned them. (Thus the frequencies in the test data don’t play a role, just the frequencies in the training data). So first we segment each test sentence word into characters. Then we apply the first rule: replace every instance of e r in the test corpus with er, and then the second rule: replace every instance of e_r_ in the test corpus with er_, and so on. By the end, if the test corpus contained the word n e w e r _, it would be tokenized as a full word. But a new (unknown) word like l o w e r _ would be merged into the two tokens low er_.

Of course in real algorithms BPE is run with many thousands of merges on a very large input corpus. The result is that most words will be represented as full symbols, and only the very rare words (and unknown words) will have to be represented by their parts.

2.4.4 Word Normalization, Lemmatization and Stemming

Word normalization is the task of putting words/tokens in a standard format, choosing a single normal form for words with multiple forms like USA and US or uh-huh and uhhuh. This standardization may be valuable, despite the spelling information that is lost in the normalization process. For information retrieval or information extraction about the US, we might want to see information from documents whether they mention the US or the USA.
Case folding is another kind of normalization. Mapping everything to lower case means that Woodchuck and woodchuck are represented identically, which is very helpful for generalization in many tasks, such as information retrieval or speech recognition. For sentiment analysis and other text classification tasks, information extraction, and machine translation, by contrast, case can be quite helpful and case folding is generally not done. This is because maintaining the difference between, for example, US the country and us the pronoun can outweigh the advantage in generalization that case folding would have provided for other words.

For many natural language processing situations we also want two morphologically different forms of a word to behave similarly. For example in web search, someone may type the string woodchucks but a useful system might want to also return pages that mention woodchuck with no s. This is especially common in morphologically complex languages like Russian, where for example the word Moscow has different endings in the phrases Moscow, of Moscow, to Moscow, and so on.

Lemmatization is the task of determining that two words have the same root, despite their surface differences. The words am, are, and is have the shared lemma be; the words dinner and dinners both have the lemma dinner. Lemmatizing each of these forms to the same lemma will let us find all mentions of words in Russian like Moscow. The lemmatized form of a sentence like He is reading detective stories would thus be He be read detective story.

How is lemmatization done? The most sophisticated methods for lemmatization involve complete morphological parsing of the word. Morphology is the study of the way words are built up from smaller meaning-bearing units called morphemes. Two broad classes of morphemes can be distinguished: stems—the central morpheme of the word, supplying the main meaning—and affixes—adding “additional” meanings of various kinds. So, for example, the word fox consists of one morpheme (the morpheme fox) and the word cats consists of two: the morpheme cat and the morpheme -s. A morphological parser takes a word like cats and parses it into the two morphemes cat and s, or parses a Spanish word like amaren (‘if in the future they would love’) into the morpheme amar ‘to love’, and the morphological features 3PL and future subjunctive.

The Porter Stemmer

Lemmatization algorithms can be complex. For this reason we sometimes make use of a simpler but cruder method, which mainly consists of chopping off word-final affixes. This naive version of morphological analysis is called stemming. One of the most widely used stemming algorithms is the Porter (1980). The Porter stemmer applied to the following paragraph:

This was not the map we found in Billy Bones’s chest, but an accurate copy, complete in all things—names and heights and soundings—with the single exception of the red crosses and the written notes.

produces the following stemmed output:

This wa not the map we found in Billi Bone s chest but an accur copi complet in all thing name and height and sound with the singl except of the red cross and the written note
the rules:

\[
\text{ATIONAL } \rightarrow \text{ATE} \quad \text{(e.g., relational } \rightarrow \text{relate)} \\
\text{ING } \rightarrow \epsilon \quad \text{if stem contains vowel (e.g., motoring } \rightarrow \text{motor)} \\
\text{SSES } \rightarrow \text{SS} \quad \text{(e.g., grasses } \rightarrow \text{grass)}
\]

Detailed rule lists for the Porter stemmer, as well as code (in Java, Python, etc.) can be found on Martin Porter’s homepage; see also the original paper (Porter, 1980).

Simple stemmers can be useful in cases where we need to collapse across different variants of the same lemma. Nonetheless, they do tend to commit errors of both over- and under-generalizing, as shown in the table below (Krovetz, 1993):

<table>
<thead>
<tr>
<th>Errors of Commission</th>
<th>Errors of Omission</th>
</tr>
</thead>
<tbody>
<tr>
<td>organization → organ</td>
<td>European → Europe</td>
</tr>
<tr>
<td>doing → doe</td>
<td>analysis → analyzes</td>
</tr>
<tr>
<td>numerical → numerous</td>
<td>noise → noisy</td>
</tr>
<tr>
<td>policy → police</td>
<td>sparse → sparsity</td>
</tr>
</tbody>
</table>

2.4.5 Sentence Segmentation

Sentence segmentation is another important step in text processing. The most useful cues for segmenting a text into sentences are punctuation, like periods, question marks, and exclamation points. Question marks and exclamation points are relatively unambiguous markers of sentence boundaries. Periods, on the other hand, are more ambiguous. The period character “.” is ambiguous between a sentence boundary marker and a marker of abbreviations like Mr. or Inc. The previous sentence that you just read showed an even more complex case of this ambiguity, in which the final period of Inc. marked both an abbreviation and the sentence boundary marker. For this reason, sentence tokenization and word tokenization may be addressed jointly.

In general, sentence tokenization methods work by first deciding (based on rules or machine learning) whether a period is part of the word or is a sentence-boundary marker. An abbreviation dictionary can help determine whether the period is part of a commonly used abbreviation; the dictionaries can be hand-built or machine-learned (Kiss and Strunk, 2006), as can the final sentence splitter. In the Stanford CoreNLP toolkit (Manning et al., 2014), for example sentence splitting is rule-based, a deterministic consequence of tokenization; a sentence ends when a sentence-ending punctuation (., !, or ?) is not already grouped with other characters into a token (such as for an abbreviation or number), optionally followed by additional final quotes or brackets.

2.5 Minimum Edit Distance

Much of natural language processing is concerned with measuring how similar two strings are. For example in spelling correction, the user typed some erroneous string—let’s say graffe—and we want to know what the user meant. The user probably intended a word that is similar to giraffe. Among candidate similar words, the word giraffe, which differs by only one letter from graffe, seems intuitively
to be more similar than, say grail or graf, which differ in more letters. Another example comes from coreference, the task of deciding whether two strings such as the following refer to the same entity:

Stanford President Marc Tessier-Lavigne
Stanford University President Marc Tessier-Lavigne

Again, the fact that these two strings are very similar (differing by only one word) seems like useful evidence for deciding that they might be coreferent.

**Edit distance** gives us a way to quantify both of these intuitions about string similarity. More formally, the **minimum edit distance** between two strings is defined as the minimum number of editing operations (operations like insertion, deletion, substitution) needed to transform one string into another.

The gap between intention and execution, for example, is 5 (delete an i, substitute e for n, substitute x for t, insert c, substitute u for n). It’s much easier to see this by looking at the most important visualization for string distances, an **alignment** between the two strings, shown in Fig. 2.14. Given two sequences, an alignment is a correspondence between substrings of the two sequences. Thus, we say I aligns with the empty string, N with E, and so on. Beneath the aligned strings is another representation; a series of symbols expressing an **operation list** for converting the top string into the bottom string: d for deletion, s for substitution, i for insertion.

![Figure 2.14](image)

We can also assign a particular cost or weight to each of these operations. The **Levenshtein** distance between two sequences is the simplest weighting factor in which each of the three operations has a cost of 1 (Levenshtein, 1966)—we assume that the substitution of a letter for itself, for example, t for t, has zero cost. The Levenshtein distance between intention and execution is 5. Levenshtein also proposed an alternative version of his metric in which each insertion or deletion has a cost of 1 and substitutions are not allowed. (This is equivalent to allowing substitution, but giving each substitution a cost of 2 since any substitution can be represented by one insertion and one deletion). Using this version, the Levenshtein distance between intention and execution is 8.

**2.5.1 The Minimum Edit Distance Algorithm**

How do we find the minimum edit distance? We can think of this as a search task, in which we are searching for the shortest path—a sequence of edits—from one string to another.

The space of all possible edits is enormous, so we can’t search naively. However, lots of distinct edit paths will end up in the same state (string), so rather than recomputing all those paths, we could just remember the shortest path to a state each time we saw it. We can do this by using **dynamic programming**.
is the name for a class of algorithms, first introduced by Bellman (1957), that apply a table-driven method to solve problems by combining solutions to sub-problems. Some of the most commonly used algorithms in natural language processing make use of dynamic programming, such as the Viterbi algorithm (Chapter 8) and the CKY algorithm for parsing (Chapter 13).

The intuition of a dynamic programming problem is that a large problem can be solved by properly combining the solutions to various sub-problems. Consider the shortest path of transformed words that represents the minimum edit distance between the strings "intention" and "execution" shown in Fig. 2.16.

Imagine some string (perhaps it is "exention") that is in this optimal path (whatever it is). The intuition of dynamic programming is that if "exention" is in the optimal operation list, then the optimal sequence must also include the optimal path from "intention" to "exention". Why? If there were a shorter path from "intention" to "exention", then we could use it instead, resulting in a shorter overall path, and the optimal sequence wouldn’t be optimal, thus leading to a contradiction.

The minimum edit distance algorithm algorithm was named by Wagner and Fischer (1974) but independently discovered by many people (see the Historical Notes section of Chapter 8).

Let’s first define the minimum edit distance between two strings. Given two strings, the source string $X$ of length $n$, and target string $Y$ of length $m$, we’ll define $D[i,j]$ as the edit distance between $X[1..i]$ and $Y[1..j]$, i.e., the first $i$ characters of $X$ and the first $j$ characters of $Y$. The edit distance between $X$ and $Y$ is thus $D[n,m]$.

We’ll use dynamic programming to compute $D[n,m]$ bottom up, combining solutions to subproblems. In the base case, with a source substring of length $i$ but an empty target string, going from $i$ characters to 0 requires $i$ deletes. With a target substring of length $j$ but an empty source going from 0 characters to $j$ characters requires $j$ inserts. Having computed $D[i,j]$ for small $i,j$ we then compute larger $D[i,j]$ based on previously computed smaller values. The value of $D[i,j]$ is computed by taking the minimum of the three possible paths through the matrix which
If we assume the version of Levenshtein distance in which the insertions and deletions each have a cost of 1 (\(\text{ins-cost}(\cdot) = \text{del-cost}(\cdot) = 1\)), and substitutions have a cost of 2 (except substitution of identical letters have zero cost), the computation for \(D[i, j]\) becomes:

\[
D[i, j] = \min \begin{cases} 
D[i-1, j] + \text{del-cost(source}[i]) \\
D[i, j-1] + \text{ins-cost(target}[j]) \\
D[i-1, j-1] + \text{sub-cost(source}[i], target}[j])
\end{cases}
\]

(2.8)

The algorithm is summarized in Fig. 2.17; Fig. 2.18 shows the results of applying the algorithm to the distance between intention and execution with the version of Levenshtein in Eq. 2.8.

---

**Function** Min-Edit-Distance(source, target) returns min-distance

\[ n \leftarrow \text{LENGTH(source)} \]
\[ m \leftarrow \text{LENGTH(target)} \]
Create a distance matrix \(D[n+1,m+1]\)

# Initialization: the zeroth row and column is the distance from the empty string
\(D[0,0] = 0\)

for each row \(i\) from 1 to \(n\) do
    \(D[i,0] \leftarrow D[i-1,0] + \text{del-cost(source}[i])\)

for each column \(j\) from 1 to \(m\) do
    \(D[0,j] \leftarrow D[0,j-1] + \text{ins-cost(target}[j])\)

# Recurrence relation:
for each row \(i\) from 1 to \(n\) do
    for each column \(j\) from 1 to \(m\) do
        \(D[i,j] \leftarrow \text{MIN}(D[i-1,j] + \text{del-cost(source}[i]), D[i,j-1] + \text{ins-cost(target}[j]), D[i-1,j-1] + \text{sub-cost(source}[i], target}[j])\)

# Termination
return \(D[n,m]\)

---

**Alignment** Knowing the minimum edit distance is useful for algorithms like finding potential spelling error corrections. But the edit distance algorithm is important in another way; with a small change, it can also provide the minimum cost alignment between two strings. Aligning two strings is useful throughout speech and language processing. In speech recognition, minimum edit distance alignment is
used to compute the word error rate (Chapter 26). Alignment plays a role in machine translation, in which sentences in a parallel corpus (a corpus with a text in two languages) need to be matched to each other.

To extend the edit distance algorithm to produce an alignment, we can start by visualizing an alignment as a path through the edit distance matrix. Figure 2.19 shows this path with the boldfaced cell. Each boldfaced cell represents an alignment of a pair of letters in the two strings. If two boldfaced cells occur in the same row, there will be an insertion in going from the source to the target; two boldfaced cells in the same column indicate a deletion.

Figure 2.19 also shows the intuition of how to compute this alignment path. The computation proceeds in two steps. In the first step, we augment the minimum edit distance algorithm to store backpointers in each cell. The backpointer from a cell points to the previous cell (or cells) that we came from in entering the current cell. We’ve shown a schematic of these backpointers in Fig. 2.19. Some cells have multiple backpointers because the minimum extension could have come from multiple previous cells. In the second step, we perform a **backtrace**. In a backtrace, we start from the last cell (at the final row and column), and follow the pointers back through the dynamic programming matrix. Each complete path between the final cell and the initial cell is a minimum distance alignment. Exercise 2.7 asks you to modify the minimum edit distance algorithm to store the pointers and compute the backtrace to output an alignment.

While we worked our example with simple Levenshtein distance, the algorithm in Fig. 2.17 allows arbitrary weights on the operations. For spelling correction, for example, substitutions are more likely to happen between letters that are next to each other on the keyboard. The **Viterbi** algorithm is a probabilistic extension of minimum edit distance. Instead of computing the “minimum edit distance” between two strings, Viterbi computes the “maximum probability alignment” of one string with another. We’ll discuss this more in Chapter 8.

### 2.6 Summary

This chapter introduced a fundamental tool in language processing, the **regular expression**, and showed how to perform basic **text normalization** tasks including
When entering a value in each cell, we mark which of the three neighboring cells we came from with up to three arrows. After the table is full we compute an alignment (minimum edit path) by using a backtrace, starting at the 8 in the lower-right corner and following the arrows back. The sequence of bold cells represents one possible minimum cost alignment between the two strings. Diagram design after Gusfield (1997).

**Figure 2.19**

word segmentation and normalization, sentence segmentation, and stemming. We also introduced the important minimum edit distance algorithm for comparing strings. Here's a summary of the main points we covered about these ideas:

- The regular expression language is a powerful tool for pattern-matching.
- Basic operations in regular expressions include concatenation of symbols, disjunction of symbols (\[\], \|, and \\.), counters (*, +, and \{n,m\}), anchors (^, $) and precedence operators ((), [).  
- **Word tokenization and normalization** are generally done by cascades of simple regular expression substitutions or finite automata.  
- The Porter algorithm is a simple and efficient way to do stemming, stripping off affixes. It does not have high accuracy but may be useful for some tasks.  
- The minimum edit distance between two strings is the minimum number of operations it takes to edit one into the other. Minimum edit distance can be computed by dynamic programming, which also results in an alignment of the two strings.

**Bibliographical and Historical Notes**

Kleene 1951: 1956 first defined regular expressions and the finite automaton, based on the McCulloch-Pitts neuron. Ken Thompson was one of the first to build regular expressions compilers into editors for text searching (Thompson, 1968). His editor ed included a command “g/regular expression/p”, or Global Regular Expression Print, which later became the Unix grep utility.

Text normalization algorithms have been applied since the beginning of the field. One of the earliest widely used stemmers was Lovins (1968). Stemming was also applied early to the digital humanities, by Packard (1973), who built an affix-stripping morphological parser for Ancient Greek. Currently a wide variety of code for tokenization and normalization is available, such as the Stanford Tokenizer (http://nlp.stanford.edu/software/tokenizer.shtml) or specialized tokenizers for Twitter (O’Connor et al., 2010), or for sentiment (http://sentiment.christopherpotts.net/tokenizing.html). See Palmer (2012) for a survey of text preprocessing. NLTK is an essential tool that offers both useful
Python libraries (http://www.nltk.org) and textbook descriptions (Bird et al., 2009) of many algorithms including text normalization and corpus interfaces.

For more on Herdan’s law and Heaps’ Law, see Herdan (1960, p. 28), Heaps (1978), Egghe (2007) and Baayen (2001); Yasseri et al. (2012) discuss the relationship with other measures of linguistic complexity. For more on edit distance, see the excellent Gusfield (1997). Our example measuring the edit distance from ‘intention’ to ‘execution’ was adapted from Kruskal (1983). There are various publicly available packages to compute edit distance, including Unix diff and the NIST sclite program (NIST, 2005).

In his autobiography Bellman (1984) explains how he originally came up with the term dynamic programming:

“...The 1950s were not good years for mathematical research. [the] Secretary of Defense ...had a pathological fear and hatred of the word, research... I decided therefore to use the word, “programming”. I wanted to get across the idea that this was dynamic, this was multi-stage... I thought, let’s ... take a word that has an absolutely precise meaning, namely dynamic... it’s impossible to use the word, dynamic, in a pejorative sense. Try thinking of some combination that will possibly give it a pejorative meaning. It’s impossible. Thus, I thought dynamic programming was a good name. It was something not even a Congressman could object to.”

Exercises

2.1 Write regular expressions for the following languages.
   1. the set of all alphabetic strings;
   2. the set of all lower case alphabetic strings ending in a b;
   3. the set of all strings from the alphabet a, b such that each a is immediately preceded by and immediately followed by a b;

2.2 Write regular expressions for the following languages. By “word”, we mean an alphabetic string separated from other words by whitespace, any relevant punctuation, line breaks, and so forth.
   1. the set of all strings with two consecutive repeated words (e.g., “Humbert Humbert” and “the the” but not “the bug” or “the big bug”);
   2. all strings that start at the beginning of the line with an integer and that end at the end of the line with a word;
   3. all strings that have both the word grotto and the word raven in them (but not, e.g., words like grottos that merely contain the word grotto);
   4. write a pattern that places the first word of an English sentence in a register. Deal with punctuation.

2.3 Implement an ELIZA-like program, using substitutions such as those described on page 10. You might want to choose a different domain than a Rogerian psychologist, although keep in mind that you would need a domain in which your program can legitimately engage in a lot of simple repetition.

2.4 Compute the edit distance (using insertion cost 1, deletion cost 1, substitution cost 1) of “leda” to “deal”. Show your work (using the edit distance grid).
2.5 Figure out whether drive is closer to brief or to divers and what the edit distance is to each. You may use any version of distance that you like.

2.6 Now implement a minimum edit distance algorithm and use your hand-computed results to check your code.

2.7 Augment the minimum edit distance algorithm to output an alignment; you will need to store pointers and add a stage to compute the backtrace.
