CHAPTER 2

Regular Expressions, Text Normalization, Edit Distance

User: You are like my father in some ways.
ELIZA: WHAT RESEMBLANCE DO YOU SEE
User: You are not very aggressive but I think you don’t want me to notice that.
ELIZA: WHAT MAKES YOU THINK I AM NOT VERY AGGRESSIVE
User: You don’t argue with me.
ELIZA: WHY DO YOU THINK I DON’T ARGUE WITH YOU
User: You are afraid of me.
ELIZA: DOES IT PLEASE YOU TO BELIEVE I AM AFRAID OF YOU

Weizenbaum (1966)

The dialogue above is from ELIZA, an early natural language processing system that could carry on a limited conversation with a user by imitating the responses of a Rogerian psychotherapist (Weizenbaum, 1966). ELIZA is a surprisingly simple program that uses pattern matching to recognize phrases like “You are X” and translate them into suitable outputs like “What makes you think I am X?”. This simple technique succeeds in this domain because ELIZA doesn’t actually need to know anything to mimic a Rogerian psychotherapist. As Weizenbaum notes, this is one of the few dialogue genres where listeners can act as if they know nothing of the world. Eliza’s mimicry of human conversation was remarkably successful: many people who interacted with ELIZA came to believe that it really understood them and their problems, many continued to believe in ELIZA’s abilities even after the program’s operation was explained to them (Weizenbaum, 1976), and even today such chatbots are a fun diversion.

Of course modern conversational agents are much more than a diversion; they can answer questions, book flights, or find restaurants, functions for which they rely on a much more sophisticated understanding of the user’s intent, as we will see in Chapter 24. Nonetheless, the simple pattern-based methods that powered ELIZA and other chatbots play a crucial role in natural language processing.

We’ll begin with the most important tool for describing text patterns: the regular expression. Regular expressions can be used to specify strings we might want to extract from a document, from transforming “You are X” in Eliza above, to defining strings like $1.99 or $24.99 for extracting tables of prices from a document.

We’ll then turn to a set of tasks collectively called text normalization, in which regular expressions play an important part. Normalizing text means converting it to a more convenient, standard form. For example, most of what we are going to do with language relies on first separating out or tokenizing words from running text, the task of tokenization. English words are often separated from each other by whitespace, but whitespace is not always sufficient. New York and rock ‘n’ roll are sometimes treated as large words despite the fact that they contain spaces, while sometimes we’ll need to separate I’m into the two words I and am. For processing tweets or texts we’ll need to tokenize emoticons like :) or hashtags like #nlp1proc. Some languages, like Chinese, don’t have spaces between words, so word tokenization becomes more difficult.
Another part of text normalization is lemmatization, the task of determining that two words have the same root, despite their surface differences. For example, the words sang, sung, and sings are forms of the verb sing. The word sing is the common lemma of these words, and a lemmatizer maps from all of these to sing. Lemmatization is essential for processing morphologically complex languages like Arabic. Stemming refers to a simpler version of lemmatization in which we mainly just strip suffixes from the end of the word. Text normalization also includes sentence segmentation: breaking up a text into individual sentences, using cues like periods or exclamation points.

Finally, we’ll need to compare words and other strings. We’ll introduce a metric called edit distance that measures how similar two strings are based on the number of edits (insertions, deletions, substitutions) it takes to change one string into the other. Edit distance is an algorithm with applications throughout language processing, from spelling correction to speech recognition to coreference resolution.

### 2.1 Regular Expressions

_SIR ANDREW: Her C’s, her U’s and her T’s: why that?_

_Shakespeare, Twelfth Night_

One of the unsung successes in standardization in computer science has been the regular expression (RE), a language for specifying text search strings. This practical language is used in every computer language, word processor, and text processing tools like the Unix tools grep or Emacs. Formally, a regular expression is an algebraic notation for characterizing a set of strings. They are particularly useful for searching in texts, when we have a pattern to search for and a corpus of texts to search through. A regular expression search function will search through the corpus, returning all texts that match the pattern. The corpus can be a single document or a collection. For example, the Unix command-line tool grep takes a regular expression and returns every line of the input document that matches the expression.

A search can be designed to return every match on a line, if there are more than one, or just the first match. In the following examples we generally underline the exact part of the pattern that matches the regular expression and show only the first match. We’ll show regular expressions delimited by slashes but note that slashes are not part of the regular expressions.

Regular expressions come in many variants. We’ll be describing extended regular expressions; different regular expression parsers may only recognize subsets of these, or treat some expressions slightly differently. Using an online regular expression tester is a handy way to test out your expressions and explore these variations.

#### 2.1.1 Basic Regular Expression Patterns

The simplest kind of regular expression is a sequence of simple characters. To search for woodchuck, we type `/woodchuck/`. The expression `/Buttercup/` matches any string containing the substring Buttercup; grep with that expression would return the line _I’m called little Buttercup_. The search string can consist of a single character (like `/!/`) or a sequence of characters (like `/urgl/`).

Regular expressions are case sensitive; lower case `/s/` is distinct from upper case `/S/` (/s/ matches a lower case s but not an upper case S). This means that the pattern `/woodchucks/` will not match the string Woodchucks. We can solve this
problem with the use of the square braces [ and ]. The string of characters inside the
braces specifies a disjunction of characters to match. For example, Fig. 2.2 shows that the pattern /[^wW]/ matches patterns containing either w or W.

The regular expression /[^1234567890]/ specified any single digit. While such
classes of characters as digits or letters are important building blocks in expressions,
they can get awkward (e.g., it’s inconvenient to specify

/^[ABCDEFHJKLMNPQRSTUWXYZ]/

to mean “any capital letter”). In cases where there is a well-defined sequence asso-
ciated with a set of characters, the brackets can be used with the dash (-) to specify
any one character in a range. The pattern /^[2-5]/ specifies any one of the charac-
ters 2, 3, 4, or 5. The pattern /^[b-g]/ specifies one of the characters b, c, d, e, f, or
"g. Some other examples are shown in Fig. 2.3.

The square braces can also be used to specify what a single character cannot be,
by use of the caret ^. If the caret ^ is the first symbol after the open square brace [
, the resulting pattern is negated. For example, the pattern /^[^a]/ matches any single
character (including special characters) except a. This is only true when the caret
is the first symbol after the open square brace. If it occurs anywhere else, it usually
stands for a caret; Fig. 2.4 shows some examples.

How can we talk about optional elements, like an optional s in woodchuck and
woodchucks? We can’t use the square brackets, because while they allow us to say
“s or S”, they don’t allow us to say “s or nothing”. For this we use the question mark
/?, which means “the preceding character or nothing”, as shown in Fig. 2.5.

We can think of the question mark as meaning “zero or one instances of the previous character”. That is, it’s a way of specifying how many of something that we want, something that is very important in regular expressions. For example, consider the language of certain sheep, which consists of strings that look like the following:

\[ \text{baa!} \]
\[ \text{baaa!} \]
\[ \text{baaaa!} \]
\[ \ldots \]

This language consists of strings with a \( b \), followed by at least two \( a \)’s, followed by an exclamation point. The set of operators that allows us to say things like “some number of \( a \)’s” are based on the asterisk or \( * \), commonly called the Kleene * (generally pronounced “cleany star”). The Kleene star means “zero or more occurrences of the immediately previous character or regular expression”. So /a*/ means “any string of zero or more \( a \)’s”. This will match \( a \) or \( aaaaaa \), but it will also match \( \text{Off Minor} \) since the string \( \text{Off Minor} \) has zero \( a \)’s. So the regular expression for matching one or more \( a \) is /aa*/ meaning one \( a \) followed by zero or more \( a \)’s. More complex patterns can also be repeated. So /([ab])*/ means “zero or more \( a \)’s or \( b \)’s” (not “zero or more right square braces”). This will match strings like \( aaaa \) or \( ababab \) or \( bbbb \).

For specifying multiple digits (useful for finding prices) we can extend /\([0-9]\)/, the regular expression for a single digit. An integer (a string of digits) is thus /\([0-9]\)[0-9]*/. (Why isn’t it just /\([0-9]\)*/?)

Sometimes it’s annoying to have to write the regular expression for digits twice, so there is a shorter way to specify “at least one” of some character. This is the Kleene +, which means “one or more occurrences of the immediately preceding character or regular expression”. Thus, the expression /\([0-9]\)+/ is the normal way to specify “a sequence of digits”. There are thus two ways to specify the sheep language: /baaa*!/ or /baa+!/.

One very important special character is the period (\./\.), a wildcard expression that matches any single character (except a carriage return), as shown in Fig. 2.6.

The wildcard is often used together with the Kleene star to mean “any string of characters”. For example, suppose we want to find any line in which a particular word, for example, \( \text{aardvark} \), appears twice. We can specify this with the regular expression /\text{aardvark}.*\text{aardvark}/.

**Anchors** are special characters that anchor regular expressions to particular places in a string. The most common anchors are the caret \( \wedge \) and the dollar sign \$. The caret \( \wedge \) matches the start of a line. The pattern /\wedge\text{The}/ matches the word \( \text{The} \) only at the
2.1  •  Regular Expressions

start of a line. Thus, the caret `^` has three uses: to match the start of a line, to indicate a negation inside of square brackets, and just to mean a caret. (What are the contexts that allow grep or Python to know which function a given caret is supposed to have?) The dollar sign `$` matches the end of a line. So the pattern `^$` is a useful pattern for matching a space at the end of a line, and `/The dog\.$/` matches a line that contains only the phrase *The dog*. (We have to use the backslash here since we want the . to mean “period” and not the wildcard.)

There are also two other anchors: `\b` matches a word boundary, and `\B` matches a non-boundary. Thus, `/\bthe\b/` matches the word *the* but not the word *other*. More technically, a “word” for the purposes of a regular expression is defined as any sequence of digits, underscores, or letters; this is based on the definition of “words” in programming languages. For example, `/\b99\b/` will match the string *99* in *There are 99 bottles of beer on the wall* (because 99 follows a space) but not 99 in *There are 299 bottles of beer on the wall* (since 99 follows a number). But it will match 99 in *$99* (since 99 follows a dollar sign ($), which is not a digit, underscore, or letter).

2.1.2  Disjunction, Grouping, and Precedence

Suppose we need to search for texts about pets; perhaps we are particularly interested in cats and dogs. In such a case, we might want to search for either the string *cat* or the string *dog*. Since we can’t use the square brackets to search for “cat or dog” (why can’t we say `/[cat|dog]/`?), we need a new operator, the disjunction operator, also called the pipe symbol `|`. The pattern `/cat|dog/` matches either the string *cat* or the string *dog*.

Sometimes we need to use this disjunction operator in the midst of a larger sequence. For example, suppose I want to search for information about pet fish for my cousin David. How can I specify both *guppy* and *guppies*? We cannot simply say `/guppy|ies/`, because that would match only the strings *guppy* and *ies*. This is because sequences like *guppy* take precedence over the disjunction operator `|`. To make the disjunction operator apply only to a specific pattern, we need to use the parenthesis operators `()` and `.`. Enclosing a pattern in parentheses makes it act like a single character for the purposes of neighboring operators like the pipe `|` and the Kleene*. So the pattern `/gupp(y|ies)/` would specify that we meant the disjunction only to apply to the suffixes *y* and *ies*.

The parenthesis operator `()` is also useful when we are using counters like the Kleene*. Unlike the `|` operator, the Kleene* operator applies by default only to a single character, not to a whole sequence. Suppose we want to match repeated instances of a string. Perhaps we have a line that has column labels of the form *Column 1 Column 2 Column 3*. The expression `/Column\[[0-9]+\]*/` will not match any number of columns; instead, it will match a single column followed by any number of spaces! The star here applies only to the space `\ ` that precedes it, not to the whole sequence. With the parentheses, we could write the expression `/\((Column\[[0-9]+\])*\)/` to match the word *Column*, followed by a number and optional spaces, the whole pattern repeated any number of times.

This idea that one operator may take precedence over another, requiring us to sometimes use parentheses to specify what we mean, is formalized by the operator precedence hierarchy for regular expressions. The following table gives the order of RE operator precedence, from highest precedence to lowest precedence.
Thus, because counters have a higher precedence than sequences, /the*/ matches thee but not the. Because sequences have a higher precedence than disjunction, /the|any/ matches the any but not theny.

Patterns can be ambiguous in another way. Consider the expression /[^a-z]*/ when matching against the text once upon a time. Since /[^a-z]*/ matches zero or more letters, this expression could match nothing, or just the first letter o, on, onc, or once. In these cases regular expressions always match the largest string they can; we say that patterns are greedy, expanding to cover as much of a string as they can.

There are, however, ways to enforce non-greedy matching, using another meaning of the ? qualifier. The operator *? is a Kleene star that matches as little text as possible. The operator +? is a Kleene plus that matches as little text as possible.

### 2.1.3 A Simple Example

Suppose we wanted to write a RE to find cases of the English article the. A simple (but incorrect) pattern might be:

/\the/  

One problem is that this pattern will miss the word when it begins a sentence and hence is capitalized (i.e., The). This might lead us to the following pattern:

/\[tT]he/  

But we will still incorrectly return texts with the embedded in other words (e.g., other or theology). So we need to specify that we want instances with a word boundary on both sides:

/\b\[tT]he\b/  

Suppose we wanted to do this without the use of /\b/. We might want this since /\b/ won’t treat underscores and numbers as word boundaries; but we might want to find the in some context where it might also have underlines or numbers nearby (the or the25). We need to specify that we want instances in which there are no alphabetic letters on either side of the the:

/\[^a-zA-Z]{tT}he[^a-zA-Z]/  

But there is still one more problem with this pattern: it won’t find the word the when it begins a line. This is because the regular expression \[^a-zA-Z\], which we used to avoid embedded instances of the, implies that there must be some single (although non-alphabetic) character before the the. We can avoid this by specifying that before the the we require either the beginning-of-line or a non-alphabetic character, and the same at the end of the line:

/\(^[^a-zA-Z]\)[tT]he\([^a-zA-Z]\)\$/  

The process we just went through was based on fixing two kinds of errors: false positives, strings that we incorrectly matched like other or there, and false negatives, strings that we incorrectly missed, like The. Addressing these two kinds of
2.1 • Regular Expressions

errors comes up again and again in implementing speech and language processing
systems. Reducing the overall error rate for an application thus involves two antag-
onistic efforts:

- Increasing **precision** (minimizing false positives)
- Increasing **recall** (minimizing false negatives)

### 2.1.4 A More Complex Example

Let’s try out a more significant example of the power of REs. Suppose we want to
build an application to help a user buy a computer on the Web. The user might want
“any machine with at least 6 GHz and 500 GB of disk space for less than $1000”.
To do this kind of retrieval, we first need to be able to look for expressions like 6
GHz or 500 GB or Mac or $999.99. In the rest of this section we’ll work out some
simple regular expressions for this task.

First, let’s complete our regular expression for prices. Here’s a regular expres-
sion for a dollar sign followed by a string of digits:

```plaintext
/\$[0-9]+/
```

Note that the `\$` character has a different function here than the end-of-line function
we discussed earlier. Most regular expression parsers are smart enough to realize
that `\$` here doesn’t mean end-of-line. (As a thought experiment, think about how
regex parsers might figure out the function of `\$` from the context.)

Now we just need to deal with fractions of dollars. We’ll add a decimal point
and two digits afterwards:

```plaintext
/\$[0-9]+\.[0-9][0-9]/
```

This pattern only allows $199.99 but not $199. We need to make the cents
optional and to make sure we’re at a word boundary:

```plaintext
/(^|\W)$[0-9]+(\.[0-9][0-9])?\b/
```

One last catch! This pattern allows prices like $199999.99 which would be far
too expensive! We need to limit the dollar

```plaintext
/(^|\W)$[0-9]{0,3}(\.[0-9][0-9])?\b/
```

How about specifications for > 6GHz processor speed? Here’s a pattern for that:

```plaintext
/\b[6-9]+\.(GHz|Gigahertz)\b/
```

Note that we use `/\.` to mean “zero or more spaces” since there might always
be extra spaces lying around. For disk space, we’ll need to allow for optional frac-
tions again (5.5 GB); note the use of `\?` for making the final `s` optional:

```plaintext
/\b[0-9]+(\.[0-9]+)?\.(GB|Gigabytes)?\b/
```

Modifying this regular expression so that it only matches more than 500 GB is
left as an exercise for the reader.

### 2.1.5 More Operators

Figure 2.7 shows some aliases for common ranges, which can be used mainly to
save typing. Besides the Kleene * and Kleene + we can also use explicit numbers as
counters, by enclosing them in curly brackets. The regular expression /{3}/ means “exactly 3 occurrences of the previous character or expression”. So /a\.\{24\}z/ will match a followed by 24 dots followed by z (but not a followed by 23 or 25 dots followed by a z).

<table>

<td></td>
</tr>
<tr>
<td>\S</td>
<td>[ˆ\s]</td>
<td>Non-whitespace</td>
<td></td>
</tr>
</tbody>
</table>

Figure 2.7 Aliases for common sets of characters.

A range of numbers can also be specified. So /{n,m}/ specifies from n to m occurrences of the previous char or expression, and /{n,}/ means at least n occurrences of the previous expression. REs for counting are summarized in Fig. 2.8.

<table>
<thead>
<tr>
<th>RE</th>

<td>at least n occurrences of the previous char or expression</td>
</tr>
<tr>
<td>{,m}</td>
<td>up to m occurrences of the previous char or expression</td>
</tr>
</tbody>
</table>

Figure 2.8 Regular expression operators for counting.

Finally, certain special characters are referred to by special notation based on the backslash (\) (see Fig. 2.9). The most common of these are the newline character \n and the tab character \t. To refer to characters that are special themselves (like ., *, [, and \), precede them with a backslash, (i.e., /\./, /\*/., /\[/, and /\\/).

### 2.1.6 Regular Expression Substitution, Capture Groups, and ELIZA

An important use of regular expressions is in substitutions. For example, the substitution operator s/regexp1/pattern/ used in Python and in Unix commands like vim or sed allows a string characterized by a regular expression to be replaced by another string:

```
s/colour/color/
```

It is often useful to be able to refer to a particular subpart of the string matching the first pattern. For example, suppose we wanted to put angle brackets around all
integers in a text, for example, changing the 35 boxes to the <35> boxes. We’d like a way to refer to the integer we’ve found so that we can easily add the brackets. To do this, we put parentheses ( and ) around the first pattern and use the number operator \1 in the second pattern to refer back. Here’s how it looks:

s/([0-9]+)/<\1>/

The parenthesis and number operators can also specify that a certain string or expression must occur twice in the text. For example, suppose we are looking for the pattern “the Xer they were, the Xer they will be”, where we want to constrain the two X’s to be the same string. We do this by surrounding the first X with the parenthesis operator, and replacing the second X with the number operator \1, as follows:

/the (.*)er they were, the \1er they will be/

Here the \1 will be replaced by whatever string matched the first item in parentheses. So this will match the bigger they were, the bigger they will be but not the bigger they were, the faster they will be.

This use of parentheses to store a pattern in memory is called a capture group. Every time a capture group is used (i.e., parentheses surround a pattern), the resulting match is stored in a numbered register. If you match two different sets of parentheses, \2 means whatever matched the second capture group. Thus

/the (.*)er they (.*) , the \1er \2/

will match the faster they ran, the faster we ran but not the faster they ran, the faster we ate. Similarly, the third capture group is stored in \3, the fourth is \4, and so on.

Parentheses thus have a double function in regular expressions; they are used to group terms for specifying the order in which operators should apply, and they are used to capture something in a register. Occasionally we might want to use parentheses for grouping, but don’t want to capture the resulting pattern in a register. In that case we use a non-capturing group, which is specified by putting the commands ?: after the open paren, in the form (?: pattern ).

/(?:some|a few) (people|cats) like some \1/

will match some cats like some cats but not some cats like some a few.

Substitutions and capture groups are very useful in implementing simple chatbots like ELIZA (Weizenbaum, 1966). Recall that ELIZA simulates a Rogerian psychologist by carrying on conversations like the following:

User1: Men are all alike.
ELIZA1: IN WHAT WAY
User2: They’re always bugging us about something or other.
ELIZA2: CAN YOU THINK OF A SPECIFIC EXAMPLE
User3: Well, my boyfriend made me come here.
ELIZA3: YOUR BOYFRIEND MADE YOU COME HERE
User4: He says I’m depressed much of the time.
ELIZA4: I AM SORRY TO HEAR YOU ARE DEPRESSED

ELIZA works by having a series or cascade of regular expression substitutions each of which matches and changes some part of the input lines. Input lines are first uppercased. The first substitutions then change all instances of MY to YOUR, and I’M to YOU ARE, and so on. The next set of substitutions matches and replaces other patterns in the input. Here are some examples:
Since multiple substitutions can apply to a given input, substitutions are assigned a rank and applied in order. Creating patterns is the topic of Exercise 2.3, and we return to the details of the ELIZA architecture in Chapter 24.

2.1.7 Lookahead assertions

Finally, there will be times when we need to predict the future: look ahead in the text to see if some pattern matches, but not advance the match cursor, so that we can then deal with the pattern if it occurs.

These lookahead assertions make use of the (? syntax that we saw in the previous section for non-capture groups. The operator (?= pattern) is true if pattern occurs, but is zero-width, i.e. the match pointer doesn’t advance. The operator (?! pattern) only returns true if a pattern does not match, but again is zero-width and doesn’t advance the cursor. Negative lookahead is commonly used when we are parsing some complex pattern but want to rule out a special case. For example suppose we want to match, at the beginning of a line, any single word that doesn’t start with “Volcano”. We can use negative lookahead to do this:

```
/^(?!Volcano)[A-Za-z]+/$
```

2.2 Words

Before we talk about processing words, we need to decide what counts as a word. Let’s start by looking at one particular corpus (plural corpora), a computer-readable collection of text or speech. For example the Brown corpus is a million-word collection of samples from 500 written English texts from different genres (newspaper, fiction, non-fiction, academic, etc.), assembled at Brown University in 1963–64 (Kučera and Francis, 1967). How many words are in the following Brown sentence?

```
He stepped out into the hall, was delighted to encounter a water brother.
```

This sentence has 13 words if we don’t count punctuation marks as words, 15 if we count punctuation. Whether we treat period (“.”), comma (“,”), and so on as words depends on the task. Punctuation is critical for finding boundaries of things (commas, periods, colons) and for identifying some aspects of meaning (question marks, exclamation marks, quotation marks). For some tasks, like part-of-speech tagging or parsing or speech synthesis, we sometimes treat punctuation marks as if they were separate words.

The Switchboard corpus of American English telephone conversations between strangers was collected in the early 1990s; it contains 2430 conversations averaging 6 minutes each, totaling 240 hours of speech and about 3 million words (Godfrey et al., 1992). Such corpora of spoken language don’t have punctuation but do introduce other complications with regard to defining words. Let’s look at one utterance from Switchboard; an utterance is the spoken correlate of a sentence:

```
I do uh main- mainly business data processing
```
This utterance has two kinds of disfluencies. The broken-off word main- is called a fragment. Words like *uh* and *um* are called fillers or filled pauses. Should we consider these to be words? Again, it depends on the application. If we are building a speech transcription system, we might want to eventually strip out the disfluencies.

But we also sometimes keep disfluencies around. Disfluencies like *uh* or *um* are actually helpful in speech recognition in predicting the upcoming word, because they may signal that the speaker is restarting the clause or idea, and so for speech recognition they are treated as regular words. Because people use different disfluencies they can also be a cue to speaker identification. In fact Clark and Fox Tree (2002) showed that *uh* and *um* have different meanings. What do you think they are?

Are capitalized tokens like *They* and uncapsulated tokens like *they* the same word? These are lumped together in some tasks (speech recognition), while for part-of-speech or named-entity tagging, capitalization is a useful feature and is retained.

How about inflected forms like *cats* versus *cat*? These two words have the same lemma *cat* but are different wordforms. A lemma is a set of lexical forms having the same stem, the same major part-of-speech, and the same word sense. The wordform is the full inflected or derived form of the word. For morphologically complex languages like Arabic, we often need to deal with lemmatization. For many tasks in English, however, wordforms are sufficient.

How many words are there in English? To answer this question we need to distinguish two ways of talking about words. Types are the number of distinct words in a corpus; if the set of words in the vocabulary is $V$, the number of types is the vocabulary size $|V|$. Tokens are the total number $N$ of running words. If we ignore punctuation, the following Brown sentence has 16 tokens and 14 types:

They picnicked by the pool, then lay back on the grass and looked at the stars.

When we speak about the number of words in the language, we are generally referring to word types.

| Corpus                              | Tokens = $N$     | Types = $|V|$   |
|-------------------------------------|------------------|----------------|
| Shakespeare                         | 884 thousand     | 31 thousand    |
| Brown corpus                        | 1 million        | 38 thousand    |
| Switchboard telephone conversations | 2.4 million      | 20 thousand    |
| COCA                                | 440 million      | 2 million      |
| Google N-grams                      | 1 trillion       | 13 million     |

Figure 2.10 Rough numbers of types and tokens for some English language corpora. The largest, the Google N-grams corpus, contains 13 million types, but this count only includes types appearing 40 or more times, so the true number would be much larger.

Fig. 2.10 shows the rough numbers of types and tokens computed from some popular English corpora. The larger the corpora we look at, the more word types we find, and in fact this relationship between the number of types $|V|$ and number of tokens $N$ is called Herdan’s Law (Herdan, 1960) or Heaps’ Law (Heaps, 1978) after its discoverers (in linguistics and information retrieval respectively). It is shown in Eq. 2.1, where $k$ and $\beta$ are positive constants, and $0 < \beta < 1$.

$$|V| = kN^\beta$$   \hspace{1cm} (2.1)

The value of $\beta$ depends on the corpus size and the genre, but at least for the large corpora in Fig. 2.10, $\beta$ ranges from .67 to .75. Roughly then we can say that
the vocabulary size for a text goes up significantly faster than the square root of its length in words.

Another measure of the number of words in the language is the number of lemmas instead of wordform types. Dictionaries can help in giving lemma counts; dictionary entries or boldface forms are a very rough upper bound on the number of lemmas (since some lemmas have multiple boldface forms). The 1989 edition of the Oxford English Dictionary had 615,000 entries.

### 2.3 Corpora

Words don’t appear out of nowhere. Any particular piece of text that we study is produced by one or more specific speakers or writers, in a specific dialect of a specific language, at a specific time, in a specific place, for a specific function.

Perhaps the most important dimension of variation is the language. NLP algorithms are most useful when they apply across many languages. The world has 7097 languages at the time of this writing, according to the online Ethnologue catalog (Simons and Fennig, 2018). Most NLP tools tend to be developed for the official languages of large industrialized nations (Chinese, English, Spanish, Arabic, etc.), but we don’t want to limit tools to just these few languages. Furthermore, most languages also have multiple varieties, such as dialects spoken in different regions or by different social groups. Thus, for example, if we’re processing text in African American Vernacular English (AAVE), a dialect spoken by millions of people in the United States, it’s important to make use of NLP tools that function with that dialect. Twitter posts written in AAVE make use of constructions like *iont* (*I don’t in Standard American English (SAE)), or *talmbout* corresponding to SAE *talking about*, both examples that influence word segmentation (Blodgett et al. 2016, Jones 2015).

It’s also quite common for speakers or writers to use multiple languages in a single communicative act, a phenomenon called code switching. Code switching is enormously common across the world; here are examples showing Spanish and (transliterated) Hindi code switching with English (Solorio et al. 2014, Jurgens et al. 2017):

(2.2) Por primera vez veo a @username actually being hateful! it was beautiful:)

*For the first time I get to see @username actually being hateful! it was beautiful:]*

(2.3) dost tha or ra- hega … dont worry … but dherya rakhe

*[“he was and will remain a friend … don’t worry … but have faith”]*

Another dimension of variation is the genre. The text that our algorithms must process might come from newswire, fiction or non-fiction books, scientific articles, Wikipedia, or religious texts. It might come from spoken genres like telephone conversations, business meetings, police body-worn cameras, medical interviews, or transcripts of television shows or movies. It might come from work situations like doctors’ notes, legal text, or parliamentary or congressional proceedings.

Text also reflects the demographic characteristics of the writer (or speaker): their age, gender, race, socio-economic class can all influence the linguistic properties of the text we are processing.

And finally, time matters too. Language changes over time, and for some languages we have good corpora of texts from different historical periods.

Because language is so situated, when developing computational models for lan-
guage processing, it’s important to consider who produced the language, in what context, for what purpose, and make sure that the models are fit to the data.

### 2.4 Text Normalization

Before almost any natural language processing of a text, the text has to be normalized. At least three tasks are commonly applied as part of any normalization process:

1. Segmenting/tokenizing words from running text
2. Normalizing word formats
3. Segmenting sentences in running text.

In the next sections we walk through each of these tasks.

#### 2.4.1 Unix tools for crude tokenization and normalization

Let’s begin with an easy, if somewhat naive version of word tokenization and normalization (and frequency computation) that can be accomplished for English solely in a single UNIX command-line, inspired by Church (1994). We’ll make use of some Unix commands: `tr`, used to systematically change particular characters in the input; `sort`, which sorts input lines in alphabetical order; and `uniq`, which collapses and counts adjacent identical lines.

For example let’s begin with the ‘complete words’ of Shakespeare in one textfile, `sh.txt`. We can use `tr` to tokenize the words by changing every sequence of non-alphabetic characters to a newline (`'A-Za-z'` means alphabetic, the `-c` option complements to non-alphabet, and the `-s` option squeezes all sequences into a single character):

```
tr -sc 'A-Za-z' '
' < sh.txt
```

The output of this command will be:

```
THE
SONNETS
by
William
Shakespeare
From
fairest
creatures
We...
```

Now that there is one word per line, we can sort the lines, and pass them to `uniq -c` which will collapse and count them:

```
tr -sc 'A-Za-z' '
' < sh.txt | sort | uniq -c
```

with the following output:

```
1945 A
72 AARON
19 ABBESS
25 Aaron
```
Alternatively, we can collapse all the upper case to lower case:

```sh
tr -sc 'A-Za-z' '\n' < sh.txt | tr A-Z a-z | sort | uniq -c
```

whose output is:

```
14725 a
97 aaron
1 abaissiez
10 abandon
2 abandoned
2 abase
1 abash
14 abate
3 abated
3 abatement
...
```

Now we can sort again to find the frequent words. The `-n` option to `sort` means to sort numerically rather than alphabetically, and the `-r` option means to sort in reverse order (highest-to-lowest):

```sh
tr -sc 'A-Za-z' '\n' < sh.txt | tr A-Z a-z | sort | uniq -c | sort -n -r
```

The results show that the most frequent words in Shakespeare, as in any other corpus, are the short function words like articles, pronouns, prepositions:

```
27378 the
26084 and
22538 i
19771 to
17481 of
14725 a
13826 you
12489 my
11318 that
11112 in
...
```

Unix tools of this sort can be very handy in building quick word count statistics for any corpus.

### 2.4.2 Word Tokenization and Normalization

The simple UNIX tools above were fine for getting rough word statistics but more sophisticated algorithms are generally necessary for **tokenization**, the task of segmenting running text into words, and **normalization**, the task of putting words/tokens in a standard format.

While the Unix command sequence just removed all the numbers and punctuation, for most NLP applications we’ll need to keep these in our tokenization. We
often want to break off punctuation as a separate token; commas are a useful piece of information for parsers, periods help indicate sentence boundaries. But we’ll often want to keep the punctuation that occurs word internally, in examples like \textit{m.p.h, Ph.D., AT&T, cap’n.} Special characters and numbers will need to be kept in prices ($45.55) and dates (01/02/06); we don’t want to segment that price into separate tokens of “45” and “55”. And there are URLs (http://www.stanford.edu), Twitter hashtags (#nlproc), or email addresses (someone@cs.colorado.edu).

Number expressions introduce other complications as well; while commas normally appear at word boundaries, commas are used inside numbers in English, every three digits: 555,500,50. Languages, and hence tokenization requirements, differ on this; many continental European languages like Spanish, French, and German, by contrast, use a comma to mark the decimal point, and spaces (or sometimes periods) where English puts commas, for example, 555 500,50.

A tokenizer can also be used to expand \textit{clitic} contractions that are marked by apostrophes, for example, converting \textit{what’re} to the two tokens \textit{what are}, and \textit{we’re} to \textit{we are}. A clitic is a part of a word that can’t stand on its own, and can only occur when it is attached to another word. Some such contractions occur in other alphabetic languages, including articles and pronouns in French (j’ai, l’homme).

Depending on the application, tokenization algorithms may also tokenize multiword expressions like \textit{New York} or \textit{rock ‘n’ roll} as a single token, which requires a multiword expression dictionary of some sort. Tokenization is thus intimately tied up with \textit{named entity detection}, the task of detecting names, dates, and organizations (Chapter 17).

One commonly used tokenization standard is known as the \textit{Penn Treebank tokenization} standard, used for the parsed corpora (treebanks) released by the Linguistic Data Consortium (LDC), the source of many useful datasets. This standard separates out clitics (doesn’t becomes \textit{does} plus \textit{n’t}), keeps hyphenated words together, and separates out all punctuation:

\begin{quote}
\textbf{Input:} “The San Francisco-based restaurant,” they said, “doesn’t charge $10”.
\end{quote}

\begin{quote}
\textbf{Output: } \begin{tabular}{l}
“”
The
San
Francisco-based
restaurant
, “
they
said
, “
does
n’t
charge
$10”,
\end{tabular}
\end{quote}

Tokens can also be \textit{normalized}, in which a single normalized form is chosen for words with multiple forms like \textit{USA} and \textit{US} or \textit{uh-huh} and \textit{uhhuh}. This standardization may be valuable, despite the spelling information that is lost in the normalization process. For information retrieval, we might want a query for \textit{US} to match a document that has \textit{USA}; for information extraction we might want to extract coherent information that is consistent across differently-spelled instances.

\textbf{Case folding} is another kind of normalization. For tasks like speech recognition and information retrieval, everything is mapped to lower case. For sentiment analysis and other text classification tasks, information extraction, and machine translation, by contrast, case is quite helpful and case folding is generally not done (losing the difference, for example, between \textit{US} the country and \textit{us} the pronoun can outweigh the advantage in generality that case folding provides).

In practice, since tokenization needs to be run before any other language processing, it is important for it to be very fast. The standard method for tokenization/normalization is therefore to use deterministic algorithms based on regular expressions compiled into very efficient finite state automata. Carefully designed deterministic algorithms can deal with the ambiguities that arise, such as the fact that the apostrophe needs to be tokenized differently when used as a genitive marker (as in \textit{the}}
book’s cover), a quotative as in ‘The other class’, she said, or in clitics like they’re.

### 2.4.3 Word Segmentation in Chinese: the MaxMatch algorithm

Some languages, including written Chinese, Japanese, and Thai, do not use spaces to mark potential word-boundaries, and so require alternative segmentation methods. In Chinese, for example, words are composed of characters known as hanzi. Each character generally represents a single morpheme and is pronounceable as a single syllable. Words are about 2.4 characters long on average. A simple algorithm that does remarkably well for segmenting Chinese, and often used as a baseline comparison for more advanced methods, is a version of greedy search called **maximum matching** or sometimes **MaxMatch**. The algorithm requires a dictionary (wordlist) of the language.

The maximum matching algorithm starts by pointing at the beginning of a string. It chooses the longest word in the dictionary that matches the input at the current position. The pointer is then advanced to the end of that word in the string. If no word matches, the pointer is instead advanced one character (creating a one-character word). The algorithm is then iteratively applied again starting from the new pointer position. Fig. 2.11 shows a version of the algorithm.

```
function MAXMATCH(sentence, dictionary) returns word sequence W
    if sentence is empty
        return empty list
    for i ← length(sentence) downto 1
        firstword = first i chars of sentence
        remainder = rest of sentence
        if InDictionary(firstword, dictionary)
            return list(firstword, MaxMatch(remainder, dictionary))
        # no word was found, so make a one-character word
        firstword = first char of sentence
        remainder = rest of sentence
        return list(firstword, MaxMatch(remainder, dictionary))
```

**Figure 2.11** The MaxMatch algorithm for word segmentation.

MaxMatch works very well on Chinese; the following example shows an application to a simple Chinese sentence using a simple Chinese lexicon available from the Linguistic Data Consortium:

**Input:** 他特别喜欢北京烤鸭  “He especially likes Peking duck”
**Output:** 他特别喜欢北京烤鸭
             He especially likes Peking duck

MaxMatch doesn’t work as well on English. To make the intuition clear, we’ll create an example by removing the spaces from the beginning of Turing’s famous quote “We can only see a short distance ahead”, producing “wecanonlyseeashortdistanceahead”. The MaxMatch results are shown below.

**Input:** wecanonlyseeashortdistanceahead
**Output:** we canon l y see ash ort distance ahead

On English the algorithm incorrectly chose canon instead of stopping at can, which left the algorithm confused and having to create single-character words 1 and
The algorithm works better in Chinese than English, because Chinese has much shorter words than English. We can quantify how well a segmenter works using a metric called **word error rate**. We compare our output segmentation with a perfect hand-segmented (‘gold’) sentence, seeing how many words differ. The word error rate is then the normalized minimum edit distance in words between our output and the gold: the number of word insertions, deletions, and substitutions divided by the length of the gold sentence in words; we’ll see in Section 2.5 how to compute edit distance. Even in Chinese, however, MaxMatch has problems, for example dealing with **unknown words** (words not in the dictionary) or genres that differ a lot from the assumptions made by the dictionary builder.

The most accurate Chinese segmentation algorithms generally use statistical **sequence models** trained via supervised machine learning on hand-segmented training sets; we’ll introduce sequence models in Chapter 8.

### 2.4.4 Collapsing words: Lemmatization and Stemming

For many natural language processing situations we want two different forms of a word to behave similarly. For example in web search, someone may type the string *woodchucks* but a useful system might want to also return pages that mention *woodchuck* with no *s*. This is especially common in morphologically complex languages like Russian, where for example the word *Moscow* has different endings in the phrases *Moscow, of Moscow, from Moscow*, and so on.

**Lemmatization** is the task of determining that two words have the same root, despite their surface differences. The words *am, are*, and *is* have the shared lemma *be*; the words *dinner* and *dinners* both have the lemma *dinner*.

Lemmatizing each of these forms to the same lemma will let us find all mentions of words like Moscow. The the lemmatized form of a sentence like *He is reading detective stories* would thus be *He be read detective story*.

How is lemmatization done? The most sophisticated methods for lemmatization involve complete **morphological parsing** of the word. **Morphology** is the study of the way words are built up from smaller meaning-bearing units called **morphemes**. Two broad classes of morphemes can be distinguished: **stems**—the central morpheme of the word, supplying the main meaning—and **affixes**—adding “additional” meanings of various kinds. So, for example, the word *fox* consists of one morpheme (the morpheme *fox*) and the word *cats* consists of two: the morpheme *cat* and the morpheme -*s*. A morphological parser takes a word like *cats* and parses it into the two morphemes *cat* and *s*, or a Spanish word like *amaren* (‘if in the future they would love’) into the morphemes *amar* ‘to love’, *3PL*, and *future subjunctive*.

#### The Porter Stemmer

Lemmatization algorithms can be complex. For this reason we sometimes make use of a simpler but cruder method, which mainly consists of chopping off word-final affixes. This naive version of morphological analysis is called **stemming**. One of the most widely used stemming algorithms is the Porter (1980). The Porter stemmer applied to the following paragraph:

> This was not the map we found in Billy Bones’s chest, but an accurate copy, complete in all things-names and heights and soundings-with the single exception of the red crosses and the written notes.
produces the following stemmed output:

```
This was not the map we found in Billi Bone's chest but an 
accur copi complet in all thing name and height and sound 
with the singl except of the red cross and the written note 
```

The algorithm is based on series of rewrite rules run in series, as a **cascade**, in 
which the output of each pass is fed as input to the next pass; here is a sampling of 
the rules:

- **ATIONAL** → **ATE** (e.g., relational → relate)
- **ING** → **ε** if stem contains vowel (e.g., motoring → motor)
- **SSES** → **SS** (e.g., grasses → grass)

Detailed rule lists for the Porter stemmer, as well as code (in Java, Python, etc.) 
can be found on Martin Porter's homepage; see also the original paper (Porter, 1980).

Simple stemmers can be useful in cases where we need to collapse across differ-
ent variants of the same lemma. Nonetheless, they do tend to commit errors of both 
over- and under-generalizing, as shown in the table below (Krovetz, 1993):

<table>
<thead>
<tr>
<th>Errors of Commission</th>
<th>Errors of Omission</th>
</tr>
</thead>
<tbody>
<tr>
<td>organization organ</td>
<td>European Europe</td>
</tr>
<tr>
<td>doing doe</td>
<td>analysis analyzes</td>
</tr>
<tr>
<td>numerical numerous</td>
<td>noise noisy</td>
</tr>
<tr>
<td>policy police</td>
<td>sparse sparsity</td>
</tr>
</tbody>
</table>

### 2.4.5 Byte-Pair Encoding

Stemming or lemmatizing has another side-benefit. By treating two similar words 
identically, these normalization methods help deal with the problem of **unknown 
words**, words that a system has not seen before.

Unknown words are particularly relevant for machine learning systems. As we 
will see in the next chapter, machine learning systems often learn some facts about 
words in one corpus (**a training** corpus) and then use these facts to make decisions 
about a separate **test** corpus and its words. Thus if our training corpus contains, say 
the words **low** and **lowest**, but not **lower**, but then the word **lower** appears in our 
test corpus, our system will not know what to do with it. Stemming or lemmatizing 
everything to **low** can solve the problem, but has the disadvantage that sometimes 
we don’t want words to be completely collapsed. For some purposes (for example 
part-of-speech tagging) the words **low** and **lower** need to remain distinct.

A solution to this problem is to use a different kind of tokenization in which 
most tokens are words, but some tokens are frequent word parts like **-er**, so that an 
unseen word can be represented by combining the parts.

The simplest such algorithm is **byte-pair encoding**, or **BPE** (Sennrich et al., 
2016). Byte-pair encoding is based on a method for text compression (Gage, 1994), 
but here we use it for tokenization instead. The intuition of the algorithm is to 
iteratively merge frequent pairs of characters.

The algorithm begins with the set of symbols equal to the set of characters. Each 
word is represented as a sequence of characters plus a special end-of-word symbol ·. At each step of the algorithm, we count the number of symbol pairs, find the 
most frequent pair (‘A’, ‘B’), and replace it with the new merged symbol (‘AB’). We 
continue to count and merge, creating new longer and longer character strings, until
we’ve done \( k \) merges; \( k \) is a parameter of the algorithm. The resulting symbol set will consist of the original set of characters plus \( k \) new symbols.

The algorithm is run inside words (we don’t merge across word boundaries). For this reason, the algorithm can take as input a dictionary of words together with counts. For example, consider the following tiny input dictionary:

<table>
<thead>
<tr>
<th>word</th>
<th>frequency</th>
</tr>
</thead>
<tbody>
<tr>
<td>low</td>
<td>5</td>
</tr>
<tr>
<td>lowest</td>
<td>2</td>
</tr>
<tr>
<td>newer</td>
<td>6</td>
</tr>
<tr>
<td>wider</td>
<td>3</td>
</tr>
<tr>
<td>new</td>
<td>2</td>
</tr>
</tbody>
</table>

We first count all pairs of symbols: the most frequent is the pair \( r \cdot \) because it occurs in newer (frequency of 6) and wider (frequency of 3) for a total of 9 occurrences. We then merge these symbols, treating \( r \cdot \) as one symbol, and count again:

<table>
<thead>
<tr>
<th>word</th>
<th>frequency</th>
</tr>
</thead>
<tbody>
<tr>
<td>low</td>
<td>5</td>
</tr>
<tr>
<td>lowest</td>
<td>2</td>
</tr>
<tr>
<td>newer</td>
<td>6</td>
</tr>
<tr>
<td>wider</td>
<td>3</td>
</tr>
<tr>
<td>new</td>
<td>2</td>
</tr>
</tbody>
</table>

Now the most frequent pair is \( e \cdot r \), which we merge:

<table>
<thead>
<tr>
<th>word</th>
<th>frequency</th>
</tr>
</thead>
<tbody>
<tr>
<td>low</td>
<td>5</td>
</tr>
<tr>
<td>lowest</td>
<td>2</td>
</tr>
<tr>
<td>newer</td>
<td>6</td>
</tr>
<tr>
<td>wider</td>
<td>3</td>
</tr>
<tr>
<td>new</td>
<td>2</td>
</tr>
</tbody>
</table>

Our system has learned that there should be a token for word-final \( er \), represented as \( er \cdot \). If we continue, the next merges are

\[
('\text{e}', 'w')
\]
\[
('\text{n}', 'ew')
\]
\[
('\text{l}', 'o')
\]
\[
('\text{lo}', 'w')
\]
\[
('\text{new}', 'er\cdot')
\]
\[
('\text{low}', 'r\cdot')
\]

The current set of symbols is thus \{·, d, e, i, l, n, o, r, s, t, w, r·, er·, ew, new, lo, low, newer, low\}

When we need to tokenize a test sentence, we just run the merges we have learned, greedily, in the order we learned them, on the test data. (Thus the frequencies in the test data don’t play a role, just the frequencies in the training data). So first we segment each test sentence word into characters. Then we apply the first rule: replace every instance of \( r \cdot \) in the test corpus with \( r \cdot \), and then the second rule: replace every instance of \( e \cdot r \) in the test corpus with \( er \cdot \), and so on. By the end, if the test corpus contained the word \( n e w e r \cdot \), it would be tokenized as a full word. But a new (unknown) word like \( l o w e r \cdot \) would be merged into the two tokens \( low \cdot er \cdot \).

Of course in real algorithms BPE is run with many thousands of merges on a very large input dictionary. The result is that most words will be represented as
full symbols, and only the very rare words (and unknown words) will have to be represented by their parts.

The full BPE learning algorithm is given in Fig. 2.12.

```python
import re, collections
def get_stats(vocab):
    pairs = collections.defaultdict(int)
    for word, freq in vocab.items():
        symbols = word.split()
        for i in range(len(symbols) - 1):
            pairs[symbols[i], symbols[i + 1]] += freq
    return pairs
def merge_vocab(pair, v_in):
    v_out = {}
    bigram = re.escape(''.join(pair))
    p = re.compile(r'(?<!\S)' + bigram + r'(?!\S)')
    for word in v_in:
        w_out = p.sub(''.join(pair), word)
        v_out[w_out] = v_in[word]
    return v_out

vocab = {'low/<wsp>' : 5, 'lowest/<wsp>' : 2, 'newer/<wsp>' : 6, 'newest/<wsp>' : 3, 'Mr.' : 2}
num_merges = 8
for i in range(num_merges):
    pairs = get_stats(vocab)
    best = max(pairs, key=pairs.get)
    vocab = merge_vocab(best, vocab)
    print(best)
```

**Figure 2.12** Python code for BPE learning algorithm from Sennrich et al. (2016).

### 2.4.6 Sentence Segmentation

**Sentence segmentation** is another important step in text processing. The most useful cues for segmenting a text into sentences are punctuation, like periods, question marks, and exclamation points. Question marks and exclamation points are relatively unambiguous markers of sentence boundaries. Periods, on the other hand, are more ambiguous. The period character "." is ambiguous between a sentence boundary marker and a marker of abbreviations like *Mr.* or *Inc.* The previous sentence that you just read showed an even more complex case of this ambiguity, in which the final period of *Inc.* marked both an abbreviation and the sentence boundary marker. For this reason, sentence tokenization and word tokenization may be addressed jointly.

In general, sentence tokenization methods work by building a binary classifier (based on a sequence of rules or on machine learning) that decides if a period is part of the word or is a sentence-boundary marker. In making this decision, it helps to know if the period is attached to a commonly used abbreviation; thus, an abbreviation dictionary is useful.

State-of-the-art methods for sentence tokenization are based on machine learning and are introduced in later chapters.
Much of natural language processing is concerned with measuring how similar two strings are. For example in spelling correction, the user typed some erroneous string—let’s say graffe—and we want to know what the user meant. The user probably intended a word that is similar to graffe. Among candidate similar words, the word giraffe, which differs by only one letter from graffe, seems intuitively to be more similar than, say, graill or graf, which differ in more letters. Another example comes from coreference, the task of deciding whether two strings such as the following refer to the same entity:

Stanford President John Hennessy
Stanford University President John Hennessy

Again, the fact that these two strings are very similar (differing by only one word) seems like useful evidence for deciding that they might be coreferent.

**Edit distance** gives us a way to quantify both of these intuitions about string similarity. More formally, the **minimum edit distance** between two strings is defined as the minimum number of editing operations (operations like insertion, deletion, substitution) needed to transform one string into another.

The gap between intention and execution, for example, is 5 (delete an i, substitute e for n, substitute x for t, insert c, substitute u for n). It’s much easier to see this by looking at the most important visualization for string distances, an **alignment** between the two strings, shown in Fig. 2.13. Given two sequences, an **alignment** is a correspondence between substrings of the two sequences. Thus, we say I aligns with the empty string, N with E, and so on. Beneath the aligned strings is another representation; a series of symbols expressing an **operation list** for converting the top string into the bottom string: d for deletion, s for substitution, i for insertion.

We can also assign a particular cost or weight to each of these operations. The **Levenshtein** distance between two sequences is the simplest weighting factor in which each of the three operations has a cost of 1 (Levenshtein, 1966)—we assume that the substitution of a letter for itself, for example, t for t, has zero cost. The Levenshtein distance between intention and execution is 5. Levenshtein also proposed an alternative version of his metric in which each insertion or deletion has a cost of 1 and substitutions are not allowed. (This is equivalent to allowing substitution, but giving each substitution a cost of 2 since any substitution can be represented by one insertion and one deletion). Using this version, the Levenshtein distance between intention and execution is 8.
2.5.1 The Minimum Edit Distance Algorithm

How do we find the minimum edit distance? We can think of this as a search task, in which we are searching for the shortest path—a sequence of edits—from one string to another.

![Diagram showing the edit distance between strings "intention" and "execution".]

The space of all possible edits is enormous, so we can’t search naively. However, lots of distinct edit paths will end up in the same state (string), so rather than re-computing all those paths, we could just remember the shortest path to a state each time we saw it. We can do this by using dynamic programming. Dynamic programming is the name for a class of algorithms, first introduced by Bellman (1957), that apply a table-driven method to solve problems by combining solutions to sub-problems. Some of the most commonly used algorithms in natural language processing make use of dynamic programming, such as the Viterbi algorithm (Chapter 8) and the CKY algorithm for parsing (Chapter 11).

The intuition of a dynamic programming problem is that a large problem can be solved by properly combining the solutions to various sub-problems. Consider the shortest path of transformed words that represents the minimum edit distance between the strings intention and execution shown in Fig. 2.15.

![Diagram showing the minimum edit distance algorithm.]

Imagine some string (perhaps it is exention) that is in this optimal path (whatever it is). The intuition of dynamic programming is that if exention is in the optimal operation list, then the optimal sequence must also include the optimal path from intention to exention. Why? If there were a shorter path from intention to exention, then we could use it instead, resulting in a shorter overall path, and the optimal sequence wouldn’t be optimal, thus leading to a contradiction.

The minimum edit distance algorithm was named by Wagner and Fischer (1974) but independently discovered by many people (see the Historical Notes section of Chapter 8).

Let’s first define the minimum edit distance between two strings. Given two strings, the source string $X$ of length $n$, and target string $Y$ of length $m$, we’ll define $D(i, j)$ as the edit distance between $X[1..i]$ and $Y[1..j]$, i.e., the first $i$ characters of $X$ and the first $j$ characters of $Y$. The edit distance between $X$ and $Y$ is thus $D(n, m)$. 
We’ll use dynamic programming to compute $D(n, m)$ bottom up, combining solutions to subproblems. In the base case, with a source substring of length $i$ but an empty target string, going from $i$ characters to 0 requires $i$ deletes. With a target substring of length $j$ but an empty source going from 0 characters to $j$ characters requires $j$ inserts. Having computed $D(i, j)$ for small $i, j$ we then compute larger $D(i, j)$ based on previously computed smaller values. The value of $D(i, j)$ is computed by taking the minimum of the three possible paths through the matrix which arrive there:

$$
D[i, j] = \min \begin{cases}
D[i-1, j] + \text{del-cost}(source[i]) \\
D[i, j-1] + \text{ins-cost}(target[j]) \\
D[i-1, j-1] + \text{sub-cost}(source[i], target[j])
\end{cases}
$$

If we assume the version of Levenshtein distance in which the insertions and deletions each have a cost of 1 ($\text{ins-cost}(\cdot) = \text{del-cost}(\cdot) = 1$), and substitutions have a cost of 2 (except substitution of identical letters have zero cost), the computation for $D(i, j)$ becomes:

$$
D[i, j] = \min \begin{cases}
D[i-1, j] + 1 \\
D[i, j-1] + 1 \\
D[i-1, j-1] + \begin{cases}
2; & \text{if } source[i] \neq target[j] \\
0; & \text{if } source[i] = target[j]
\end{cases}
\end{cases}
$$

(2.4)

The algorithm is summarized in Fig. 2.16; Fig. 2.17 shows the results of applying the algorithm to the distance between intention and execution with the version of Levenshtein in Eq. 2.4.

Knowing the minimum edit distance is useful for algorithms like finding potential spelling error corrections. But the edit distance algorithm is important in another way; with a small change, it can also provide the minimum cost alignment between two strings. Aligning two strings is useful throughout speech and language processing. In speech recognition, minimum edit distance alignment is used to compute the word error rate (Chapter 26). Alignment plays a role in machine translation, in which sentences in a parallel corpus (a corpus with a text in two languages) need to be matched to each other.

To extend the edit distance algorithm to produce an alignment, we can start by visualizing an alignment as a path through the edit distance matrix. Figure 2.18 shows this path with the boldfaced cell. Each boldfaced cell represents an alignment of a pair of letters in the two strings. If two boldfaced cells occur in the same row, there will be an insertion in going from the source to the target; two boldfaced cells in the same column indicate a deletion.

Figure 2.18 also shows the intuition of how to compute this alignment path. The computation proceeds in two steps. In the first step, we augment the minimum edit distance algorithm to store backpointers in each cell. The backpointer from a cell points to the previous cell (or cells) that we came from in entering the current cell. We’ve shown a schematic of these backpointers in Fig. 2.18. Some cells have multiple backpointers because the minimum extension could have come from multiple previous cells. In the second step, we perform a backtrace. In a backtrace, we start from the last cell (at the final row and column), and follow the pointers back through the dynamic programming matrix. Each complete path between the final cell and the initial cell is a minimum distance alignment. Exercise 2.7 asks you to modify the
function \textsc{Min-Edit-Distance}(source, target) returns \textit{min-distance}

\begin{verbatim}
 n ← LENGTH(source)
m ← LENGTH(target)
Create a distance matrix \textit{distance}[n+1,m+1]

# Initialization: the zeroth row and column is the distance from the empty string
D[0,0] = 0
for each row \textit{i} from 1 to \textit{n} do
    D[i,0] ← D[i-1,0] + \textit{del-cost}(source[\textit{i}])
for each column \textit{j} from 1 to \textit{m} do
    D[0,j] ← D[0,j-1] + \textit{ins-cost}(target[\textit{j}])

# Recurrence relation:
for each row \textit{i} from 1 to \textit{n} do
    for each column \textit{j} from 1 to \textit{m} do
        D[i,j] ← \textsc{MIN}(D[i-1,j] + \textit{del-cost}(source[\textit{i}]),
                        D[i,j-1] + \textit{sub-cost}(source[\textit{i}],target[\textit{j}]),
                        D[i-1,j-1] + \textit{ins-cost}(target[\textit{j}]))

# Termination
return D[n,m]
\end{verbatim}

Figure 2.16  The minimum edit distance algorithm, an example of the class of dynamic programming algorithms. The various costs can either be fixed (e.g., \(\forall x, \text{ins-cost}(x) = 1\)) or can be specific to the letter (to model the fact that some letters are more likely to be inserted than others). We assume that there is no cost for substituting a letter for itself (i.e., \(\text{sub-cost}(x,x) = 0\)).

Figure 2.17  Computation of minimum edit distance between \textit{intention} and \textit{execution} with the algorithm of Fig. 2.16, using Levenshtein distance with cost of 1 for insertions or deletions, 2 for substitutions.

minimum edit distance algorithm to store the pointers and compute the backtrace to output an alignment.

While we worked our example with simple Levenshtein distance, the algorithm in Fig. 2.16 allows arbitrary weights on the operations. For spelling correction, for example, substitutions are more likely to happen between letters that are next to each other on the keyboard. The \textbf{Viterbi} algorithm is a probabilistic extension of minimum edit distance. Instead of computing the “minimum edit distance” between two strings, Viterbi computes the “maximum probability alignment” of one string with another. We’ll discuss this more in Chapter 8.
### 2.6 Summary

This chapter introduced a fundamental tool in language processing, the regular expression, and showed how to perform basic text normalization tasks including word segmentation and normalization, sentence segmentation, and stemming. We also introduce the important minimum edit distance algorithm for comparing strings. Here’s a summary of the main points we covered about these ideas:

- The regular expression language is a powerful tool for pattern-matching.
- Basic operations in regular expressions include concatenation of symbols, disjunction of symbols (|), counters (*, +, and {n,m}), anchors (^, $) and precedence operators ((), ).
- Word tokenization and normalization are generally done by cascades of simple regular expressions substitutions or finite automata.
- The Porter algorithm is a simple and efficient way to do stemming, stripping off affixes. It does not have high accuracy but may be useful for some tasks.
- The minimum edit distance between two strings is the minimum number of operations it takes to edit one into the other. Minimum edit distance can be computed by dynamic programming, which also results in an alignment of the two strings.

#### Bibliographical and Historical Notes

Kleene (1951) and (1956) first defined regular expressions and the finite automaton, based on the McCulloch-Pitts neuron. Ken Thompson was one of the first to build regular expressions compilers into editors for text searching (Thompson, 1968). His editor ed included a command “/regular expression/p”, or Global Regular Expression Print, which later became the Unix grep utility.

Text normalization algorithms has been applied since the beginning of the field. One of the earliest widely-used stemmers was Lovins (1968). Stemming was also applied early to the digital humanities, by Packard (1973), who built an affix-stripping morphological parser for Ancient Greek. Currently a wide variety of code for tok-

Figure 2.18 When entering a value in each cell, we mark which of the three neighboring cells we came from with up to three arrows. After the table is full we compute an alignment (minimum edit path) by using a backtrace, starting at the 8 in the lower-right corner and following the arrows back. The sequence of bold cells represents one possible minimum cost alignment between the two strings. Diagram design after Gusfield (1997).
enization and normalization is available, such as the Stanford Tokenizer (http://nlp.stanford.edu/software/tokenizer.shtml) or specialized tokenizers for Twitter (O’Connor et al., 2010), or for sentiment (http://sentiment.christopherpotts.net/tokenizing.html). See Palmer (2012) for a survey of text preprocessing. While the max-match algorithm we describe is commonly used as a segmentation baseline in languages like Chinese, higher accuracy algorithms like the Stanford CRF segmenter, are based on sequence models; see Tseng et al. (2005) and Chang et al. (2008). NLTK is an essential tool that offers both useful Python libraries (http://www.nltk.org) and textbook descriptions (Bird et al., 2009) of many algorithms including text normalization and corpus interfaces.

For more on Herdan’s law and Heaps’ Law, see Herdan (1960, p. 28), Heaps (1978), Egghe (2007) and Baayen (2001); Yasseri et al. (2012) discuss the relationship with other measures of linguistic complexity. For more on edit distance, see the excellent Gusfield (1997). Our example measuring the edit distance from ‘intention’ to ‘execution’ was adapted from Kruskal (1983). There are various publicly available packages to compute edit distance, including Unix diff and the NIST sclite program (NIST, 2005).

In his autobiography Bellman (1984) explains how he originally came up with the term dynamic programming:

“...The 1950s were not good years for mathematical research. [the] Secretary of Defense ...had a pathological fear and hatred of the word, research... I decided therefore to use the word, “programming”. I wanted to get across the idea that this was dynamic, this was multi-stage... I thought, let’s ... take a word that has an absolutely precise meaning, namely dynamic... it’s impossible to use the word, dynamic, in a pejorative sense. Try thinking of some combination that will possibly give it a pejorative meaning. It’s impossible. Thus, I thought dynamic programming was a good name. It was something not even a Congressman could object to.”

Exercises

2.1 Write regular expressions for the following languages.

1. the set of all alphabetic strings;
2. the set of all lower case alphabetic strings ending in a b;
3. the set of all strings from the alphabet a, b such that each a is immediately preceded by and immediately followed by a b;

2.2 Write regular expressions for the following languages. By “word”, we mean an alphabetic string separated from other words by whitespace, any relevant punctuation, line breaks, and so forth.

1. the set of all strings with two consecutive repeated words (e.g., “Humbert Humbert” and “the the” but not “the bug” or “the big bug”);
2. all strings that start at the beginning of the line with an integer and that end at the end of the line with a word;
3. all strings that have both the word grotto and the word raven in them (but not, e.g., words like grottos that merely contain the word grotto);
4. write a pattern that places the first word of an English sentence in a register. Deal with punctuation.

2.3 Implement an ELIZA-like program, using substitutions such as those described on page 9. You might want to choose a different domain than a Rogerian psychologist, although keep in mind that you would need a domain in which your program can legitimately engage in a lot of simple repetition.

2.4 Compute the edit distance (using insertion cost 1, deletion cost 1, substitution cost 1) of “leda” to “deal”. Show your work (using the edit distance grid).

2.5 Figure out whether drive is closer to brief or to divers and what the edit distance is to each. You may use any version of distance that you like.

2.6 Now implement a minimum edit distance algorithm and use your hand-computed results to check your code.

2.7 Augment the minimum edit distance algorithm to output an alignment; you will need to store pointers and add a stage to compute the backtrace.

2.8 Implement the MaxMatch algorithm.

2.9 To test how well your MaxMatch algorithm works, create a test set by removing spaces from a set of sentences. Implement the Word Error Rate metric (the number of word insertions + deletions + substitutions, divided by the length in words of the correct string) and compute the WER for your test set.
