We present a model as well as experimental results for a surface electrode radio-frequency Paul trap that has a circular electrode geometry well-suited for trapping of single ions and two-dimensional planar ion crystals. The trap design is compatible with microfabrication and offers a simple method by which the height of the trapped ions above the surface may be changed in situ. We demonstrate trapping of single 88Sr+ ions over an ion height range of 200–1000 µm for several hours under Doppler laser cooling, and use these to characterize the trap, finding good agreement with our model.

PACS numbers: pacs

An array of trapped ions in optical cavities, connected by a network of optical fibers, represents a possible distributed architecture for large-scale quantum information processing (QIP) [1]. The realization of an ion-based quantum network, at the scale of tens and hundreds of qubits, strongly motivates the integration of optics in surface-electrode ion traps [2, 3]. However, the potential benefits of integrated optics have long been overshadowed by the challenges of trapping ions in the proximity of dielectrics [4], as well as the difficulty of guaranteeing good spatial overlap of the trapped ion with the field mode of the integrated optical element.

In the past, there have been demonstrations of integration of bulk optics at ~10 mm distance [5–7] into traps that were of the linear four-rod Paul trap design. More recently, the integration of multi-mode optical fibers [8] and microscopic reflective optics [9] for the collection of ion fluorescence has been demonstrated in microfabricated surface-electrode designs. Complementing such work on light collection, the present work demonstrates integrated light delivery and micrometer-scale tuning of the ion-fiber mode overlap in a scalable, surface-electrode point Paul trap with an integrated single-mode (SM) fiber. A key contrast between previous and current work is in the physical characteristics of the optical mode. Whereas light collection is achieved by the nearby placement of a high numerical aperture (NA) element in the vicinity of the ion’s isotropic fluorescence, light delivery through a single-mode optical fiber involves a highly-directional Gaussian beam with a mode waist of a few tens of micrometers at the ion position. These dimensions place stringent demands on the relative alignment of the trapping fields and the integrated structure. Future developments in optics integration, such as microcavities for the realization of quantum light-matter interfaces in the framework of cavity quantum electrodynamics (cQED), or lensed fibers for faster gate times and optical trapping of ions [10], will employ sub-10 µm waists [9], thereby placing even further demands on the precise construction of the ion-mode overlap.

Building upon previous work in translation of a trapped ion using segmented RF electrodes [8, 11, 12], we demonstrate micron-scale, micromotion-free positioning of the ion in the mode of the integrated fiber. Previous work on this problem have often utilized a technically challenging setup in which the trap electrodes were adjusted mechanically [13], which is inapplicable when elements are integrated directly onto the trap structure. On the other hand, translation of the ion position by DC potentials suffers from increased micromotion as the ion is displaced from the node of the trapping RF field, which lead to broadening of the atomic transitions that significantly limits the usefulness of DC translation [14]. Micromotion-free ion translation in a surface-electrode trap, as demonstrated here over the mode of an integrated fiber, is an enabling technology for the realization of large-scale planar trap integration such as the optical array as envisioned in Ref. [X] as it resolves the challenge of variations and uncertainties arising from device fabrication.

The article is organized as follows: first, we describe the assembly of the fiber-integrated surface-electrode trap and the experimental setup. We then demonstrate fiber-ion interaction and a scheme for quantifying the coupling strength. Finally, we discuss the technique of ion translation through segmented RF electrodes, and present the measurement of the fiber mode profile obtained by translating the ion along a horizontal axis of the planar trap.

We approach the challenge of integrated light delivery by using the fiber itself as part of the trap structure. Fig. 1(a) shows a schematic of the ion trap design, which is a modified version of the surface-electrode point Paul trap described recently [12, 15]. The center, grounded electrode has a diameter of 1.0 mm. The elliptical RF pad has a major-axis diameter of 5.9 mm and a minor-axis diameter of 2.8 mm, and is shifted with respect to the center of the ground electrode by 500 µm. This design achieves an ion height of 670 µm. Asymmetries uniquely define the principal axes of the trap, which are tilted by 28° in the yz-plane for efficient cooling and micromotion compensation. The side electrodes are used for DC com-
The ferrule is evident in the form of a 70 μm-diameter optical ferrule whose tip is conventionally prepared (i.e. cured in F112 fiber epoxy and polished) in a stainless steel SMA ferrule whose tip is aligned with respect to the minor axis of the trap. The fiber core approximately 50 μm nonconcentricity with respect to the trap electrodes. The ferrule is rotated until the fiber core is aligned with the minor axis of the trap. (c) Image of the fiber-integrated trap mounted on the CPGA and installed on the 8 K basplate of the closed-cycle cryostat.

The optical fiber is SM for the 674 nm quadrupole transition of ⁸⁸Sr⁺, which is of particular interest for QIP with trapped ions as it forms the basis for the qubit in several implementations [16]. The fiber has a cladding diameter of 125 μm and a core diameter of 3 ± 0.5 μm, and is conventionally prepared (i.e. cured in F112 fiber epoxy and polished) in a stainless steel SMA ferrule whose tip has been machined to the proper diameter for mating with the via of the PCB. The incorporation of the ferrule provides mechanical robustness for the subsequent assembly and install. The attachment of PCB and ferrule is performed under an optical microscope, as shown in Fig. 1(b) where gross imprecision in the machining of the ferrule is evident in the form of 70 μm nonconcentricity between the fiber and the ferrule. The ferrule is rotated with respect to the PCB in order to place the fiber core roughly along the minor axis of the trap, and was cured using cyanoacrylate adhesive. According to numerical simulation of the trap design, the final placement of the fiber core along deviates by about 50 μm from the predicted trap location.

The fiber-integrated trap is installed on a ceramic pin grid array (CPGA) and mounted on the 8 K baseplate of the closed-cycle cryostat [17] as shown in Fig. 1(c). The fiber is routed through a hole in the CPGA and a hole in a flange of the vacuum chamber, where it is sealed in place with TorrSeal UHV epoxy. (The epoxy is applied over the 900μm-diameter PVC jacket of the fiber.) The trap is operated at a typical RF frequency of 2π · 6 MHz and 250 Vpp amplitude, achieving secular frequencies of ωₓ′ = 2π · 410 kHz, ωᵧ = 2π · 240 kHz, ωᵧ′ = 2π · 170 kHz. We produce ⁸⁸Sr⁺ ions by resonant photoionization, which are Doppler cooled on the 5S₁/₂ ↔ 5P₁/₂ transition at 422 nm, while simultaneously driving the 4D₃/₂ ↔ 5P₁/₂ transition at 1092 nm [see ⁸⁸Sr⁺ level diagram in Fig. 2(a)]. Ion fluorescence at 422 nm is collected by a 0.5 NA lens inside the chamber and imaged onto a CCD camera and a photomultiplier tube (PMT), both with individual ion resolution. We ensure that the ions are located at the nodal point of the RF field by minimizing the micromotion amplitude using the correlation measurement technique [14]. As the Doppler beam has nonzero projection along all three principal axes of the pseudopotential, the ion is positioned on the RF node exactly when the micromotion amplitude is eliminated.

The basic interaction between the ion and the fiber light is demonstrated by coupling 674 nm light into the fiber and observing the rate at which the ion is trans-
ferred to the metastable $4D_{5/2}$ state, while the ion is radially illuminated by the 422 nm and 1092 nm beams. Upon shelving the ion to the $4D_{5/2}$ state, no 422 nm photons are scattered, and the ion remains dark until it decays spontaneously back to the $5S_{1/2}$ state. An example of such a telegraph scan is shown in Fig. 2(b). The interaction strength on the $5S_{1/2} \leftrightarrow 4D_{5/2}$ transition can then be quantified in terms of shelving probability, by computing the statistics of dark periods over a long (1 minute) measurement period. Fig. 2(c) shows the increase in shelving probability as a function of 674 nm power coupled to the trap fiber.

In the current instance of the fiber-integrated trap, the fiber mode waist at the location of the ion is expected to be few tens of micrometers whereas the mechanical assembly of the ferrule and PCB resulted in an ion-fiber displacement of about 50 $\mu$m along the minor axis. Because of the exponential fall-off in intensity along the transverse plane of a Gaussian mode, such offsets can dramatically diminish the interaction strength for cQED experiments, thereby demanding an in situ control for the transverse positioning of a trapped ion.

In contrast to DC potentials, the ion can be translated by the use of segmented RF electrodes without incurring micromotion. In this scheme, the nodal point of the Paul trap is translated by the superposition of additional RF fields. It is important to maintain either perfect in-phase or out-of-phase drives for the multiple sources, as any other relative phase will result in excess micromotion. A simple way to achieve in-phase drive is to use a network of capacitors to couple a single RF source onto multiple electrodes, as shown in Fig. 3(a). Capacitances $C_1$ and $C_2$ are intrinsic to the trap electrodes and chamber wiring, as is $C_{12}$, the intrinsic capacitive coupling between the two electrodes. We introduce a mechanically tunable capacitor $C_v = 0.5 - 30$ pF in order to adjust the coupling amplitude. Because the ion-fiber displacement lies predominantly along the minor axis of the trap, we have introduced the second RF on a side electrode on the minor axis. The extent of ion translation is parameterized by the ratio of RF amplitudes $\delta = V_2/V_1$, and the displacement of the RF node from the initial trapping point as a function of $\delta$ is shown in Fig. 3(b). Experimental verification of our numerical modeling was shown in previous work with the symmetric point Paul trap [12] as well as a calibration of the image based on two-ion spacing at a known secular frequency. The RF amplitudes are monitored by a matched pair of capacitive dividers directly on $V_1$ and $V_2$, with overall detector quantization error of 2 Vpp.

Fig. 4 shows the result of translating the ion across the mode of the integrated fiber using the RF method. The graph shows the shelving probability into the dark $4D_{5/2}$ state versus ion position as measured from the initial trapping point of single RF. The images (a), (b) and (c) show the ion displaced relative to the (unfocused) image of the fiber. Based on these measurements of the mode profile, we find that the fiber mode has a waist of 20 $\pm$ 1 $\mu$m and that the original trap location was offset from the mode by $-74.5 \pm 0.5$ microns along the minor axis of the trap. Using an estimate of 2 V in RF volt-
age measurement error, we also find that points (a), (b) and (c) are offset $-78.8 \pm 1.6 \, \mu m$, $-8.4 \pm 3.4 \, \mu m$ and $4.1 \pm 3.6 \, \mu m$ from the fiber mode, respectively. The position uncertainties are only limited by the control and measurement of RF amplitudes; the node defined by multiple RFs, in principle, is not distinct from that of single RF operation. Additionally, we have trapped and compensated ions as far as 500 $\mu m$ away from the initial trapping point (by shorting $V_1$ and $V_2$), verifying the significant range of the RF translation technique.

With the ion tuned over the fiber mode, we have looked for effects of dielectric charging by the 674 nm fiber light. The ion was illuminated by 125 $\mu W$ of 674 nm trap light while being simultaneously repumped out of the dark $4^2D_{5/2}$ state on the 1033 nm $4D_{5/2} \leftrightarrow 5P_{3/2}$ transition. The amplitude of ion micromotion was recorded for several minutes under different conditions of fiber light. We find similar constancy of the micromotion amplitude, as shown in the inset of Fig. 4, thereby implying no detectable charging of the dielectric due to activation of fiber light at an ion height of 700 − 800 $\mu m$.

In conclusion, we have demonstrated micrometer positioning of a trapped ion in a surface-electrode trap with an integrated optical fiber. The ion was placed 4.1 ± 3.6 $\mu m$ from the peak of the fiber mode, despite an initial $-78.8 \pm 0.6 \, \mu m$ fiber-ion mismatch due to the assembly of the trap. In the present demonstration, the accuracy in placement in terms of the mode waist is $\chi = 3.6\mu m/23.7\mu m = 0.15$, which corresponds to a 4% variation in mode intensity from the peak of the mode. Given the analogy between the Gaussian mode of the integrated fiber with the optical mode of proposed microcavities for cQED experiments [9], the technique of segmented RFs could be crucial for attaining strong coupling between a single trapped ion and a cavity photon. Moreover, an integrated trap that utilizes the fiber facet as one of the mirrors of an optical cavity could serve as a node in a distributed QIP architecture where the photon state can be extracted through the fiber [1].

We expect the in situ control of the ion position to be a useful general technique for future development of surface-electrode ion traps with integrated elements, as it alleviates the strict requirements on modeling and fabrication. While we have incorporated a SM, step-index fiber for the delivery of 674 nm for the $^{88}\text{Sr}^+$ ion, the assembly process is compatible with more advanced fiber systems, such as lensed fibers that achieve very high intensities for faster gate times, endlessly single-mode photonic crystal fibers which can propagate all relevant trapping and manipulation lasers through a single integrated port, or hollow-core fibers that may permit the efficient coupling of ion systems to neutral atoms [18]. The positioning ability is also relevant for other types of integration, such as the coupling of a trapped ion to superconducting devices on the surface of a cryogenically operated trap [19].

The ability to vary the ion height without incurring micromotion is also of tremendous value in the search for the origin of anomalous heating in ion traps [20, 21]. For this application, the integrated fiber permits study of the heating dynamics along the direction normal to the trap surface, in addition to the radial axis that is more commonly investigated. Furthermore, the ion may be placed over various materials on the surface of a single trap, in order to study material dependences without introducing random errors associated with the fabrication of individual trap samples.
