From Ukkonen to McCreight and Weiner:
A Unifying View of Linear-Time
Suffix Tree Construction

Abstract. We review the linear time suffix tree constructions by Weiner, McCreight, and Ukkonen. We use the terminology of the most recent algorithm, Ukkonen’s online construction, to explain its historic predecessors. This reveals relationships much closer than one would expect, since the three algorithms are based on rather different intuitive ideas. Moreover, it completely explains the differences between these algorithms in terms of simplicity, efficiency, and implementation complexity.

Key Words. Text processing. Online string matching. Suffix trees. Linear time algorithm. Program transformation.

1 Motivation and Overview

Suffix trees provide most efficient solutions to a “myriad” [4] of string processing problems. The suffix tree for a string $t$ really turns $t$ inside out, immediately exposing properties like longest or most frequent subwords. The fundamental question whether $w$ occurs in $t$ can be answered in $O(|w|)$ steps — independent of the length of $t$ — once the suffix tree for $t$ is constructed. Thus it is of great importance that the suffix tree for $t$ can be constructed and represented in linear time and space.

In spite of their basic role for string processing, elementary books on algorithms and data structures barely mention suffix trees, and never give efficient algorithms for their construction [3, 21, 11, 1, 17, 7]. Recent exceptions are [22, 13]. The reason for this is historical: starting with the seminal paper by Weiner [26], suffix tree construction has built up a reputation of being overly complicated. The purpose of the present paper is to correct this reputation — by working out what is essential about efficient suffix tree construction, and what is unnecessary complexity.

*Work supported by a grant from the International Computer Science Institute, Berkeley, CA.
More precisely, we review the linear time algorithms of Weiner [26], McCreight [19], and Ukkonen [25]. Let us call these algorithms \textit{wrf},\footnote{wrf stands for the historic name “Weiner’s repetition finder” used in [20].} \textit{mcc}, and \textit{ukk}.

We use the terminology of the most recent algorithm, Ukkonen’s online construction, to explain its predecessors. This reveals relationships much closer than one would expect, since the three algorithms are based on rather different intuitive ideas. Moreover, it completely explains the differences between these algorithms in terms of simplicity, efficiency, and implementation complexity.

In Section 2, we take some time to carefully establish the terminology necessary for suffix tree construction. New aspects of this section are a more generalized definition of suffix links, and observations concerning their duality with reverse prefix trees.

Section 3 gives an exposition of Ukkonen’s and McCreight’s algorithm on a very abstract level, showing that their different intuitive ideas lead to the same sequence of tree constructing operations. The two following sections make this observation more precise. A derivation of Ukkonen’s algorithm is given (Section 4), and then Ukkonen’s is transformed into McCreight’s algorithm. Section 5 explains the transformation steps.

Section 6 revisits Weiner’s algorithm. In a sense that is made precise there, \textit{wrf} is shown as a version of \textit{ukk} working on the “wrong” tree. Section 7 concludes.

As you see from this overview, the purpose of this paper is purely academic — no new algorithms, no improvements of old ones. Just a few explanations about how the known ones relate. If you have ever been puzzled by the complexity of linear time suffix tree construction, we hope you will enjoy just reading through Sections 2, 3, and 6. The more technical material in Section 4 and 5 may be safely spared out for a later reading.

## 2 Suffix Trees and their Duality Properties

### 2.1 \(A^+\)-Trees and Suffix Trees

Let \(A\) be a finite set, the \textit{alphabet}. The elements of \(A\) are \textit{characters}. \(\varepsilon\) denotes the \textit{empty string}, \(A^*\) denotes the set of \textit{strings over} \(A\), and \(A^+ = A^* \setminus \{\varepsilon\}\). We use \(a, c, d, e\) to denote characters, and \(b, p, q, s, t, u, v, w, x, y, z\) to denote strings. The \textit{reverse} of \(t = t_1 \ldots t_n\) is \(t_n \ldots t_1\), also denoted by \(t^{-1}\). If \(t = uvw\) for some (possibly empty) \(u, v, w\), then \(u\) is a \textit{prefix} of \(t\), \(v\) is a \textit{t-word} and \(w\) is a \textit{suffix} of \(t\). A prefix or suffix of \(t\) is \textit{proper}, if it is different from \(t\). A suffix or prefix of \(t\) is \textit{nested}, if it occurs elsewhere in \(t\). Notice that \(s\) is a nested suffix of \(t\), if and only if \(s^{-1}\) is a nested prefix of \(t^{-1}\). We call a \textit{t-word} \(w\) \textit{right-branching} (\textit{left-branching}) in \(t\), if there are different characters \(a\) and \(c\), such that \(wa\) and \(cw\) (\(aw\) and \(cw\)) are \(t\)-words. Of course, \(w\) is right-branching in \(t\), if and only if \(w^{-1}\) is left-branching in \(t^{-1}\).

**Definition 2.1 (\(A^+\)-tree)**

An \(A^+\)-tree \(T\) is a rooted tree with edge labels from \(A^+\). For each \(a \in A\), every node \(k\) in \(T\) has at most one \(a\)-edge \(k \xrightarrow{a} k'\). \(\square\)
Suffix trees will be introduced below as a special form of \(A^+\)-trees. However, most of the terminology used with suffix tree construction applies to \(A^+\)-trees as well, so we present it first.

Let \(T\) be an \(A^+\)-tree. By \(\text{path}(k)\) we denote the concatenation of the edge labels on the path from the root of \(T\) to the node \(k\). Due to the requirement of unique \(a\)-edges at each node of \(T\), path labels are also unique and we can denote \(k\) by \(\overline{w}\), if and only if \(\text{path}(k) = w\). Moreover, by \(T_{\overline{w}}\) we denote the subtree of \(T\) at node \(\overline{w}\).

**Definition 2.2** (Words represented in an \(A^+\)-tree)

A string \(w\) occurs in \(T\), if and only if \(T\) contains a node \(\overline{uw}\), for some \(u\). By \(\text{words}(T)\) we denote the set of strings occurring in \(T\). For all \(s \in \text{words}(T)\) we call \((\overline{b}, u)\) reference pair of \(s\) with respect to \(T\), if \(b\) is a node in \(T\) and \(s = bu\). If \(b\) is the longest such prefix of \(s\), then \((\overline{b}, u)\) is the canonical reference pair of \(s\) with respect to \(T\). In such a case we write \(\widehat{s} = (\overline{b}, u)\).

A canonical reference pair of the form \((\overline{b}, \varepsilon)\) will be called explicit node, since it denotes the node \(b\) in \(T\). A canonical reference pair \((\overline{b}, aw)\) will be called implicit node, since the node \(\overline{baw}\) does not exist in \(T\), but can be seen “inside” the edge \(\overline{baw} \to \overline{bawv}\).

**Definition 2.3** (Atomic and compact \(A^+\)-trees)

\(T\) is atomic, if every edge in \(T\) is marked by a single character. \(T\) is compact, if every node in \(T\) is either the root, a leaf, or a branching node.

Atomic \(A^+\)-trees are also known under the name “trie” [2]. Both atomic and compact \(A^+\)-trees are uniquely determined by the words occurring in them. In an atomic \(A^+\)-tree every node is explicit. In a compact \(A^+\)-tree, nodes with a single outgoing edge are implicit nodes.

**Definition 2.4** (Suffix trees)

1. A suffix tree for \(t\) is an \(A^+\)-tree \(T\), s.t. \(\text{words}(T) = \{w \mid w\ \text{is a } t\text{-word}\}\).

2. The atomic suffix tree for \(t\) is denoted by \(\text{ast}(t)\).

3. The compact suffix tree for \(t\) is denoted by \(\text{cst}(t)\).

4. \(\text{ast}(t^{-1})\) and \(\text{cst}(t^{-1})\) are called atomic and compact reverse prefix tree for \(t\), respectively.

Figure 1 shows different suffix trees for the string \(aeceaceae\).

The reverse prefix tree is, of course, nothing new, but just the suffix tree for \(t^{-1}\). It will play an important role in explaining suffix tree constructions. We refine our notation by writing \(\overline{w}^{-1}\) instead of \(\overline{w}^{-1}\) for a node in a reverse prefix tree.

To decide whether a word \(w\) occurs in \(T\) takes \(O(|w|)\) steps: check if there is a path in \(T\) labeled \(w\). This efficient access to all subwords of \(t\) is the raison d'être of suffix trees.

The following is known about the space requirements for representing atomic and compact suffix trees (and holds for reverse prefix trees alike):

3
Figure 1: Different Suffix Trees for the String \( aecaceae \)

1. \( ast(t) \) has \( O(n^2) \) nodes (take e.g. \( t = a^n c^n \) in Figure 4). However, isomorphic subtrees\(^2\) can be shared [10]. Sharing brings the space requirements down to \( O(n) \) [8, 12]. However, subtree sharing may be impossible, when leaves are to be annotated with extra information.

2. \( cst(t) \) has \( O(n) \) nodes, as all inner nodes are branching, and there are at most \( n \) leaves. The edge labels can be represented in constant space by a pair of indices into \( t \). This is necessary to achieve a theoretical worst case bound of \( O(n) \). In practice, this is quite a delicate choice of representation in a virtual memory environment. Traversing the tree and reading the edge labels will create random-like accesses into \( t \), and can lead to performance problems with the memory subsystem.

2.2 Open Edges

A particularly convenient representation of edges which lead to a leaf node (leaf edges, for short) was introduced in [25]. The label of a leaf edge always extends to the end of the actually scanned prefix of \( t \). We may as well represent an index pair \((i, |t|)\) by \((i, \infty)\), with \( \infty \) denoting \(|t|\), whatever its value is. This means that if \( t \) is extended to the right, the label of the leaf edge grows implicitly, and the leaf continues to represent a complete suffix of (the extended) \( t \). This representation is called “open edge”. It will play a crucial part in the following sections. With a little speculation, we might even say: if Weiner had seen this idea in 1973, he would have designed Ukkonen’s algorithm then (and it would be in all textbooks today). We shall return to this in Section 6.

\(^2\)Two \( A^+ \)-trees \( T \) and \( T' \) are isomorphic, if there is a bijection \( \varphi \) between the node sets of \( T \) and \( T' \), s.t. \( u \rightarrow v \) is an edge in \( T \), if and only if \( \varphi(u) \rightarrow \varphi(v) \) is an edge in \( T' \).
2.3 Active Suffixes and Prefixes

The following notion plays a central part in all constructions:

**Definition 2.5** (Active suffix and prefix)
The active suffix of $t$ is its longest nested suffix, denoted $\alpha(t)$. The active prefix of $t$ is its longest nested prefix, denoted $\alpha^{-1}(t)$. □

With this notation, we have $\alpha(t^{-1}) = (\alpha^{-1}(t))^{-1}$.

The node $(\overline{v},v)$ representing the active suffix of $t$ in $\text{cst}(t)$ is the neuralgic point of the suffix tree. If $t$ is to be extended to the right by another character, changes in the tree structure (if any) will start at this point. Correspondingly, the active prefix node will respond to extensions of $t$ on the left. This behavior is proved and spelled out in detail in later sections.

McCreight uses functions *head* and *tail* that split a suffix $s$ of $t$ into an initial part that already occurs to the left, and the remainder. We can define them in the following way.

**Definition 2.6** (*head* and *tail*)
Let $t = us$ for some strings $u$ and $s$. *head*($s$) is the longest prefix $x$ of $s$, such that $x$ is a nested suffix of $ux$. *tail*($s$) is defined by $s = \text{head}(s) \text{tail}(s)$. □

2.4 The Role of the Sentinel Character

If $s$ is a nested suffix of $t$, then a suffix tree for $t$ does not contain a leaf $\overline{s}$. It is often convenient to add to $t$ a sentinel character, say $\$$, that does not occur in $t$. Then $t\$$ has no nested suffix, except for the empty string, i.e. each non-empty suffix of $t\$$ uniquely corresponds to a leaf in a suffix tree $T$ for $t\$$.

Considering a $t$-word $w$ and the node $\overline{w}$ in $T$, the number of leaves of $T_{\overline{w}}$ is equal to the number of positions in $t$ where $w$ occurs:

**Definition 2.7** (Suffix-Rests)
For a node $\overline{w}$ in a suffix tree $T$ for $t$, let $\text{suffixRests}_T(\overline{w}) = \{ s \mid w.s \text{ is a suffix of } t \}$. □

Clearly, $\text{suffixRests}_T(\overline{w})$ uniquely determines the shape of $T_{\overline{w}}$. But can $\text{suffixRests}_T(\overline{w})$ be determined from the edge labels of $T_{\overline{w}}$? The answer is Yes, if there is the sentinel, since then there is the leaf $\overline{ws}$ for every $s \in \text{suffixRests}_T(\overline{w})$. The answer is No without the sentinel, as can be seen for $T_{\overline{\$}}$ in $T = \text{cst}(ddacda)$ as shown in Figure 2.
It often simplifies proofs and constructions considerably to assume the presence of the sentinel character. Only in contexts where \( t \) may be expanded to the right (e.g. during online construction), the requirement for a unique final character does not make sense.

In the subsequent sections, the sentinel character is not assumed unless we explicitly say so.

### 2.5 Suffix Links

For construction and many applications of \( \mathcal{A}^+ \)-trees it is convenient to augment \( \mathcal{A}^+ \)-trees with auxiliary edges that connect nodes quite unrelated in the tree structure:

**Definition 2.8** (Suffix Links)
Consider an \( \mathcal{A}^+ \)-tree \( T \). Let \( \underline{aw} \) be a node in \( T \), and \( v \) be the longest suffix of \( w \), such that \( \underline{v} \) is also a node in \( T \). An unlabeled edge \( \underline{aw} \rightarrow \underline{v} \) is a *suffix link* in \( T \). A suffix link \( \underline{aw} \rightarrow \underline{w} \) is called *atomic*. □

Notice that node \( \underline{v} \) is well defined, since \( \underline{z} \) is a node and \( \varepsilon \) is a suffix of \( w \).

When the \( \mathcal{A}^+ \)-tree is a trie, suffix links are identical to the failure transitions of [2]. The name suffix link is due to [19]. Some authors also define a link for the *root*: \( \underline{z} \rightarrow \underline{z} \). We found that this obscures the algorithms as well as the observations in Section 2.6.

**Proposition 2.9**

1. In the atomic suffix tree for \( t \), all suffix links are atomic.

2. In the compact suffix tree for \( t\$ \), all suffix links are atomic.

**Proof**

1. This follows from the definitions, since all nodes in \( ast(t) \) are explicit.

2. We must show that for each node \( \underline{aw} \), \( \underline{w} \) is also a node in \( cst(t\$) \). \( \underline{aw} \) is either a branching node, or a leaf. Hence \( aw \) is right-branching or a non-nested suffix of \( t\$ \). But then the same holds for \( w \), and so \( \underline{w} \) is a node in \( cst(t) \). □

What if we drop the sentinel in the case of assertion 2? The suffix links for all inner nodes in \( cst(t) \) are atomic. For a leaf \( \underline{aw} \), \( w \) may be nested (due to the lack of \( \$ \)) and not right-branching, so there is no (explicit) node \( \underline{v} \). In this case, we have a non-atomic suffix link \( \underline{aw} \rightarrow \underline{v} \) for some proper suffix \( v \) of \( w \). Note that this link is the only possible exception, with all other suffix links in \( cst(t) \) being atomic.

Suffix links are the key to efficient sequential suffix tree construction, but there is more to them than this.

The atomic suffix tree of \( t \), augmented by suffix links, can be seen as a two-head automaton. Denoting the two heads by \([ \) and \( ] \), we can represent a configuration as \( u[v]w \), where

- \( uv \) is the scanned part,
Figure 3: An $A^+$-tree and its Suffix Link Tree

- $v$ is the memorized part, and
- $w$ is the unread part of the input string.

Now if $v = ay$ and $w = cx$, there are two possible transitions:

- $u[ay]\text{cx} \sim u[ayc]\text{x}$ by following the edge $\overrightarrow{ay} \rightarrow ay\text{c}$,
- $u[ay]\text{cx} \sim ua[y]\text{c}\text{x}$ by following the suffix link $\overrightarrow{ay} \rightarrow y$.

This view is taken from [20]. It nicely summarizes the additional power of suffix links that makes them useful in many contexts. For example, such an automaton can be used to compute the matching statistics in [9], the $q$-gram distance [24], or the shift-table for the Boyer-Moore algorithm [18].

2.6 Dualities between Suffix Trees and Suffix Links

We now study the deeper relation between suffix trees and their suffix links. First we note that the suffix links form a tree themselves.

**Definition 2.10** The suffix link tree $T^{-1}$ of an $A^+$-tree $T$ has a node $\overrightarrow{w}$ for each node $\overrightarrow{w}$ of $T$, and an edge $\overrightarrow{w} \rightarrow \overrightarrow{wv}$ when $\overrightarrow{w} \rightarrow \overrightarrow{wv}$ is a suffix link in $T$. $\square$

It is easy to confirm that $T^{-1}$ is in fact a tree, since each node in $T$ has exactly one suffix link, which designates its parent in $T^{-1}$. The notation $T^{-1}$ will be justified by our subsequent results.

For an arbitrary $A^+$-tree $T$, $T^{-1}$ is generally not an $A^+$-tree, as can be seen in Figure 3: node $\overrightarrow{w}$ has two $d$-edges. But this changes when $T$ is a suffix tree:

**Proposition 2.11** (Duality for atomic suffix trees) $(ast(t))^{-1} = ast(t^{-1})$. In words: the suffix link tree of an atomic suffix tree is the reverse prefix tree.

**Proof** There is an edge $\overrightarrow{w} \rightarrow \overrightarrow{aw}$ in $(ast(t))^{-1}$, iff there is a suffix link $\overrightarrow{aw} \rightarrow \overrightarrow{w}$ in $ast(t)$, iff there are nodes $\overrightarrow{w}$ and $\overrightarrow{aw}$ in $ast(t)$, iff there are nodes $\overrightarrow{w}$ and $\overrightarrow{aw}$ in $ast(t^{-1})$, iff there is an edge $\overrightarrow{w} \rightarrow \overrightarrow{aw}$ in $ast(t^{-1})$. $\square$
Figure 4 shows $ast(aaaccc)$ and $ast(aaaccc^{-1})$. Solid edges represent $ast(aaaccc)$, while dotted edges (without their labels) represent the suffix links. Vice versa for $ast(aaaccc^{-1})$.

The reason why this duality is not widely known is that when considering the compact suffix tree (our main object of interest), it is obscured by the fact that the explicit nodes of a compact suffix tree and the corresponding reverse prefix tree do not coincide. But a weaker form of duality still holds:

**Proposition 2.12** (Weak duality for compact suffix trees)

1. $(cst(t))^{-1}$ is an $\mathcal{A}^{+}$-tree.
2. $(cst(t))^{-1}$ represents a subset of the words represented by $cst(t^{-1})$.
3. $((cst(t))^{-1})^{-1} = cst(t)$.

**Proof**

1. Assume there is a node $\overline{w}$ in the suffix link tree that has two $a$-edges. This means that in $cst(t)$ we have suffix links $uaw \overline{w}$ and $vaw \overline{w}$ with $u \neq \varepsilon$ and $v \neq \varepsilon$. $aw$ is not a node, since otherwise, the links would point to $aw$.

   - Suppose $uaw$ or $vaw$ is an inner node. Then $uaw$ or $vaw$ is right-branching in $t$, and so must be $aw$. So $aw$ must be a node, which is a contradiction.

   - Suppose $uaw$ and $vaw$ are leaves. Without restriction to generality $vaw$ is a suffix of $uaw$, and it is longer than $w$. Hence there can be no suffix link $uaw \overline{w}$.

2. The suffix link chain from $\overline{w}$ to $\overline{v}$ in $cst(t)$ yields a path labeled $w^{-1}$ in the suffix link tree. Of course, $w^{-1}$ is a $t^{-1}$-word.

3. Because of Statement 1, $(cst(t))^{-1}$ is an $\mathcal{A}^{+}$-tree, so $((cst(t))^{-1})^{-1}$ is defined. The node set is unchanged under the $()^{-1}$ operation, except for reversal of node names. There is a suffix link $\overline{vw} \overline{v}$ in $(cst(t))^{-1}$, iff there is no suffix $r^{-1}$ of $(vw)^{-1}$, s.t. $\overline{v}$ is a node and $|vw| |r^{-1}| > |v^{-1}|$, iff there is no prefix $r$ of $vw$, s.t. $\overline{v}$ is a node and $|vw| > |v^{-1}| > |v|$, iff $cst(t)$ has an edge $\overline{vw} \overline{w}$. □
Proposition 2.12.1 can be slightly generalized: if \( T \) is (any sort of) suffix tree of some string \( t \), then \( T^{-1} \) is an \( \mathcal{A}^+ \)-tree. The reverse of this statement does not hold. For example, let \( T \) be an \( \mathcal{A}^+ \)-tree representing the words \( aa \) and \( bb \). Then \( T^{-1} \neq T \). Thus \( T^{-1} \) is an \( \mathcal{A}^+ \)-tree, but \( T \) is not a suffix tree.

A \( t^{-1} \)-word \( w^{-1} \) is not represented in the suffix link tree, if \( w \) is neither right-branching in \( t \) nor a suffix of \( t \). (Adding the sentinel does not change this situation.) This is also why \((cst(t))^{-1}\) is not a subtree of \( cst(t^{-1})\): some nodes of \((cst(t))^{-1}\) are not nodes in \( cst(t^{-1})\). But in the precise sense of Proposition 2.12, the suffix link tree approximates the reverse prefix tree. By duality, \( cst(t) \) itself approximates the prefix links of \( cst(t^{-1}) \).

At this point, it seems natural to ask whether suffix/prefix trees can be subsumed by a more general data structure in \( \mathcal{O}(n) \) space, which has the duality as an inherent property. In fact, the suffix trees recently introduced by Støyde [23] are such a self-dual data structure. However, this is beyond the scope of the present paper.

We now turn to suffix tree constructions.

3 An Abstract Comparison of ukk and mcc

\( ukk \) reads \( t \) from left to right, character by character, and incrementally constructs suffix trees for the prefixes of \( t \) seen so far. With \( ukk \), labels of open edges grow implicitly as \( t \) is read, while some edges are split and new open edges are inserted explicitly. The intermediate trees when constructing \( cst(adad) \) using \( ukk \) are shown in the left column of Figure 5.

\( mcc \) inserts the suffixes of \( t \) into an initially empty tree. Starting with the longest suffix, the method is not online, and the intermediate trees are not suffix trees. For a suffix \( s \) of \( t \) let \( T(s) \) denote the \( \mathcal{A}^+ \)-tree representing the suffixes of \( t \) that are longer than or equal to \( s \). The
right column of Figure 5 shows the intermediate trees when constructing $T(c) = cst(adadec)$ using \textit{mec}.

Let us introduce two abstract tree construction operations:

- \textit{split}(\overline{u}, v) replaces an edge $\overline{u} \xrightarrow{v} w$ by two edges $\overline{u} \xrightarrow{v} u \xrightarrow{w} v \xrightarrow{w}$

- \textit{add}(\overline{u}, a \ldots) adds a new edge from node $\overline{u}$ to a leaf, labeled $a \ldots$

Note that the \textit{add}-operation abstracts from whether the edge label is entered fully or left open to grow later. The central observation of this section is the following: the intermediate trees of \textit{ukk} and \textit{mec} are both constructed by the same sequence of abstract operations! However, these operations are applied to the intermediate trees in a different way. Both are shown in Table 1

Analogies on an abstract level often break down when you go to a more concrete level of presentation. In our case we have abstracted from a number of aspects which are essential in making both \textit{ukk} and \textit{mec} linear time algorithms. But when we take these into account, our analogy still persists. Let us summarize what will be shown in full detail in Sections 4 and 5.

1. \textit{ukk} can be transformed into \textit{mec} by a modification of its control structure, leaving the sequence of tree constructing operations invariant.

2. This modification is a slight optimization. Under a fair implementation of the related data structures, it will give \textit{mec} a minor efficiency advantage over \textit{ukk}, on every possible input.

3. This transformation sacrifices the online property. \textit{mec} will always read ahead of \textit{ukk} in $t$. This lookahead is quantified in Proposition 5.5.

Assertion 2 is confirmed by the measurements in [16]. In fact, this invariance of the relative efficiency of \textit{ukk} and \textit{mec} made us first wonder about a deeper relationship between these two algorithms. We were incited further by a note in [25], where Ukkonen remarks that on the technical level, the main difference between \textit{ukk} and \textit{mec} lies in the way in which character reads and suffix link traversals are arranged over the loops of the program. Our study confirms, concretizes, and explains this observation.
4 Development of ukk and mcc

4.1 A Short Derivation of ukk

Space does not allow a complete derivation of ukk here. We only give a short explanation together with the concrete algorithm, and refer the reader to the development in [25] or [16].

Online construction means generating a series of suffix trees for longer and longer prefixes of $t$. While $cst(\varepsilon)$ is trivial (just the root with no edges), we study the step from $cst(p)$ to $cst(pa)$, where $p$ is a prefix of $t$, and $a$ is the next character in $t$ to be read. To construct $cst(pa)$ we have to insert some suffixes of $pa$ into $cst(p)$. Let $sa$ be a suffix of $pa$. ukk is based on the following observations about suffixes:

- If $|sa| > |\alpha(p)a|$ then $s$ is not a nested suffix of $p$ and thus $s$ corresponds to a leaf in $cst(p)$. In such a case $sa$ will correspond to the same leaf in $cst(pa)$ by the implicit growing of the corresponding open edge.

- If $|\alpha(pa)| \geq |sa| > |\alpha(pa)|$ then $sa$ is a relevant suffix of $pa$, and a new leaf $\overline{sa}$ must be introduced.

- If $|\alpha(pa)| \geq |sa|$ then no action is required, since $sa$ already occurs in $cst(p)$.

In ukk a suffix $s$ is represented by its canonical reference pair. To make reference pairs canonical we use a function canonize. When the relevant suffixes of $pa$ are processed in their natural order, i.e. by decreasing length from $\alpha(p)a$ to (excluding) $\alpha(pa)$, the corresponding canonical reference pairs can be accessed via the suffix links.

With the prefix $p$ of $t$ globally given, ukk takes four arguments with each call:

- $T = cst(p)$.
- the set $L$ of suffix links in $T$.
- the canonical reference pair $(\overline{b}, u)$ of $\alpha(p)$,
- the position $i$, such that $p = t_1 \ldots t_{i-1}$ and $t_i$ is the next input character to be read.

For convenience let us denote $\overline{b}$ by $L(\overline{b})$, whenever $\overline{b} \rightarrow \overline{b}' \in L$.

The access from one canonical reference pair to the next is accomplished by a function link, which is defined as follows:

$$\text{link}(T, L, (\overline{b}, \varepsilon)) = \begin{cases} (\overline{b}, \varepsilon), & \text{if } \overline{b} = \text{root} \\ (L(\overline{b}), \varepsilon), & \text{otherwise} \end{cases}$$

$$\text{link}(T, L, (\overline{b}, cw)) = \begin{cases} \text{canonize}(T, (\overline{b}, w)), & \text{if } \overline{b} = \text{root} \\ \text{canonize}(T, (L(\overline{b}), cw)), & \text{otherwise} \end{cases}$$

Let $n = |t|$. ukk is simply an iteration of a function update that inserts the relevant suffixes.

$$\text{ukk}(T, L, (\overline{b}, u), i) = \begin{cases} T, & \text{if } i = n + 1 \\ \text{ukk}(T', L', (\overline{b}', u'), i + 1), & \text{otherwise} \end{cases}$$

where $(T', L', (\overline{b}', u')) = \text{update}(T, L, (\overline{b}, u), i)$
To construct $\text{cst}(t)$, the initial call of $\text{ukk}$ is $\text{ukk}(\emptyset, \emptyset, (\text{root}, \varepsilon), 1)$. Now let us define the function $\text{update}$. For each relevant suffix, $\text{update}$ creates (if necessary) a new branching node by edge splitting, and sets its suffix link. It adds a new open edge for the new suffix, and advances $(\overline{b}, u)$ via the suffix link to the next suffix, until the canonical reference pair of $\alpha(\text{pl}_i)$ is reached. The function $\text{canonize}$ is applied whenever the right component of a reference pair is extended by a new character. As indicated in Section 2, edge labels are now implemented as index pairs. The pair $(l, r)$ denotes the label $t_i \ldots t_r$, while $(i, \infty)$ denotes the suffix $t_i \ldots$.

$$\text{update}(T, L, (\overline{b}, \varepsilon), i) = \begin{cases} (T, L, \text{canonize}(T, (\overline{b}, t_i))), & \text{if } \overline{b} \text{ has a } t_i\text{-edge} \\ (T \cup ((\overline{b}, \varepsilon), i), L, (\overline{b}, \varepsilon), i)), & \text{else if } \overline{b} = \text{root} \\ \text{update}(T \cup ((\overline{b}, \varepsilon), i), L, (L(\overline{b}), \varepsilon), i), & \text{otherwise} \end{cases}$$

$$\text{update}(T, L, (\overline{b}, cw), i) = \begin{cases} (T, L, \text{canonize}(T, (\overline{b}, cw t_i))), & \text{if } t_{i+w} = t_i \\ \text{update}(T \cup ((\overline{b}, cw), i), L', (\overline{b}, u'), i), & \text{otherwise} \end{cases}$$

where $\overline{b}^{(l, r)}\overline{p}$ is a c-edge

$$((\overline{b}, u') = \text{link}(T, L, (\overline{b}, cw))$$

$$L' = L \cup \{(\overline{bw}, \overline{bu'})\}$$

The expression $T \cup ((\overline{b}, \varepsilon), i)$ denotes the $A^+$-tree that results from inserting the suffix but$_i \ldots$ into $T$. It is formally defined as follows:

$$T \cup ((\overline{b}, \varepsilon), i) = T \cup \{\overline{b}^{(i, \infty)}\overline{b}_i\}$$

$$T \cup ((\overline{b}, cw), i) = (T \setminus \{\overline{b}^{(l, r)}\overline{p}\}) \cup \{\overline{b}^{(l, k)}\overline{bw}^{(l+1, r)}\overline{p}, \overline{bw}^{(i, \infty)}\overline{b}_i\}$$

where $\overline{b}^{(l, r)}\overline{p}$ is a c-edge

$$k = l + |w|$$

The first equation for $\cup$ implements the abstract $\text{add}$-operation of Section 3. The second equation corresponds to a $\text{split}/\text{add}$-combination.

### 4.2 A Short Description of $\text{mcc}$

Before we embark on the derivation of $\text{mcc}$ from $\text{ukk}$, we give a short intuitive description of our target. The complete algorithm will be given in Section 5, at the end of our transformation series.

$mcc$ constructs $\text{cst}(t)$ by successively inserting the suffixes of $t$ into an initially empty tree, from longest to shortest. It produces a sequence

$$\text{cst}(\varepsilon), T(t_1 \ldots t_n), T(t_2 \ldots t_n), \ldots, T(t_{n-1} t_n), T(t_n) = \text{cst}(t)$$

of compact $A^+$-trees, of which only the first and the last one is a suffix tree. The initial step of $\text{mcc}$ is trivial: $T(t) = T(t_1 \ldots t_n)$ is obtained from $\text{cst}(\varepsilon)$ by inserting the longest suffix $t$. Thus, $T(t)$ is the compact $A^+$-tree with only one edge $\text{root} \overrightarrow{T}$. Let $\overline{x}$ be a suffix of $t$, and suppose $x = \text{head}(as)$. For the step from $T(as)$ to $T(s)$, $\text{mcc}$ first determines $\text{tail}(s)$ and the canonical reference pair $\overline{y}$ of $y = \text{head}(s)$ in constant time from $\overline{x}$ and $\text{tail}(as)$. This is accomplished by following suffix links and scanning downward in the actual tree using a function $\text{scan}$ (see Section 5.1). Then it constructs $T(s)$ from $T(as)$ by splitting for the node $\overline{y}$ (if necessary) and adding a leaf edge labeled $\text{tail}(s)$. 

5 Transforming ukk into mcc

5.1 A Series of Program Transformations from ukk to mcc

mcc assumes that $t$ ends with a sentinel. We will assume the like in the rest of this section.

In Figure 5 we saw that ukk produces a sequence

$$cst(\varepsilon), cst(t_1), cst(t_1t_2), \ldots, cst(t),$$

which might contain a subsequence of suffix trees, in which only the leaves grow implicitly with the length of the input string. In the sequence of trees produced by mcc there are no such “non-essential” subsequences, i.e. every step produces a tree of a different structure. In the following we show that it is in fact the additional “non-essential” steps in ukk that make the difference between both algorithms. Technically, we transform ukk stepwise into equivalent functions ukk$ _1$, ukk$ _2$, and ukk$ _3$, such that ukk$ _3$ does only “essential” derivation steps. Equivalence means that for $k = 1, 2, 3$ we have $ukk(\emptyset, \emptyset, (\text{root}, \varepsilon), 1) = ukk_k(\emptyset, \emptyset, (\text{root}, \varepsilon), 1)$, and that linear time complexity is preserved. From ukk$ _3$ we synthesize a definition of mcc.

**Definition 5.1** (Essential Steps)

A derivation step $ukk_k(T, L, (\overline{b}, w), i) \Rightarrow ukk_k(T', L', (\overline{b}, q), j), k = 1, 2, 3$ is essential, if the set of edges in $T'$ is different from the set of edges in $T$. □

The first transformation step does not affect the essential steps. It simply eliminates the function update in ukk, yielding an equivalent function $ukk_1$:

\[
ukk_1(T, L, (\overline{b}, \varepsilon), i) = \begin{cases} 
T, & \text{if } i = n + 1 \\
ukk_1(T, L, \text{canonize}(T, (\overline{b}, t_i)), i + 1), & \text{else if } \overline{b} \text{ has a } t_i\text{-edge} \\
ukk_1(T \cup ((\overline{b}, \varepsilon), i), L, (\overline{b}, \varepsilon), i + 1), & \text{else if } \overline{b} = \text{root} \\
ukk_1(T \cup ((\overline{b}, \varepsilon), i), L, (L(\overline{b}), \varepsilon), i), & \text{otherwise}
\end{cases}
\]

\[
ukk_1(T, L, (\overline{b}, cw), i) = \begin{cases} 
T, & \text{if } i = n + 1 \\
ukk_1(T, L, \text{canonize}(T, (\overline{b}, cwt_i)), i + 1), & \text{else if } t_{i+|cw|} = t_i \\
ukk_1(T \cup ((\overline{b}, cw), i), L', (\overline{b}', u'), i), & \text{otherwise}
\end{cases}
\]

where $\overline{b}'$ is an $i$-edge in $T$ is a $c$-edge

\[
(\overline{b}', u') = \text{link}(T, L, (\overline{b}, cw))
\]

$L' = L \cup \{ (\overline{b}w, \overline{b}'u') \}$

To develop ukk$ _2$ we need the following lemmas.

**Lemma 5.2** Let $csa$ be a relevant suffix of $pa$, such that $s$ is not a right-branching $p$-word. Then $sa$ is a relevant suffix of $pa$.

**Proof** By assumption, csa is a nested suffix of $p$. This implies that $s$ is a nested suffix of $p$, i.e. $p = vsdw$, for some strings $v, w$ and some character $d$. Since $csa$ is not a $p$-word, we have $d \neq a$. Suppose $p = v'sdw'w'$ for some character $d'$ and some strings $v'$ and $w'$. Then $d = d'$, since otherwise $s$ would be right-branching in $p$. Hence $d' \neq a$, i.e. $sa$ is not a $p$-word. Thus $sa$ is a relevant suffix of $pa$. □

**Lemma 5.3** Consider a derivation $(\ast)$ $\epsilon_0 = ukk_1(\emptyset, \emptyset, (\text{root}, \varepsilon), 1) \Rightarrow \epsilon_1 \cdots \Rightarrow \epsilon_N = cst(t)$.
1. $e_N = \text{cst}(t)$ is derived from $e_{N-1}$ by an application of equation (1).

2. Assume that $e_{k+1}$ is derived from $e_k$ by an application of equation (6). Then we have $0 < k < N - 1$ and $e_k$ is derived from $e_{k-1}$ by an application of equation (2) or (6).

Proof

1. Let $e_{N-1} = ukk_1(T, L, (\overline{b}, q), i + 1)$, such that $i = n$. Let $p = t_1 \ldots t_{i-1}$ and assume that $q \neq \varepsilon$. Then $e_{N-1}$ is derived from $e_{N-2} = (T, L, (\overline{b}, w), i)$ by an application of equation (2) or equation (6). Hence $\text{bw}t_i$ occurs in $T$, i.e. $\text{bw}t_i$ is a $p$-word and thus the character $t_i$ occurs in $p$. This is a contradiction, since $t_i$ is the sentinel in $t$. Hence $q = \varepsilon$, i.e. $e_N$ is derived from $e_{N-1}$ by an application of equation (1).

2. We have $k > 0$, since equation (6) can not be applied to $e_0$: $k < n - 1$ follows from Statement 1. $e_k$ could not be derived from $e_{k-1}$ by an application of equation (1), (3), (4), or (5), since this would lead to an expression, to which equation (6) is not applicable. We show that this is also true for equation (7). Assume that $e_k$ is derived from $e_{k-1}$ by an application of equation (7). Hence $e_{k-1} = ukk_1(T, L, (\overline{b}, cw), i)$ and $e_k = ukk_1(T \cup ((\overline{b}, cw), i), L', (\overline{b'}, u'), i)$, where $(\overline{b'}, u') = \text{link}(T, L, (\overline{b}, cw))$ and $L' = L \cup \{(bcw, \overline{b' u'})\}$. By assumption, $u' \neq \varepsilon$. Let $p = t_1 \ldots t_{i-1}$ and $a = t_i$. Now observe that $bcua$ is a relevant suffix of $pa$ and that $b'u'$ is not right-branching in $p$. By Lemma 5.2, $b'u'a$ is a relevant suffix of $pa$, i.e. $b'u'a$ is not a $p$-word. Hence $b'u'a$ does not occur in $\text{cst}(p)$ and therefore not in $T \cup ((\overline{b}, cw), i)$. Thus $t_{i+1} \in \overline{d} \neq t_i$ and equation (6) is not applicable to $e_k$, which is a contradiction. Hence $e_k$ is derived from $e_{k-1}$ by equation (2) or (6). □

Consider a maximal subderivation $e_k \Rightarrow \cdots \Rightarrow e_{k+m+1}$ of derivation (·), in which only equation (2) or (6) are applied. By Lemma 5.3, Statement 2, we can conclude that $e_{k+1}$ is derived from $e_k$ by an application of equation (2). If $e_k = (T, L, (\overline{b}, \varepsilon), i)$ then $e_{k+m+1} = (T, L, (\overline{b}, q), j)$ is the information we need to insert the suffix $bt_l t_{l+1} \cdots$ into $T$. We have $ht_l t_{l+1} \cdots = bt_l t_{l+1} \cdots$, such that $(\overline{b}, q)$ is the canonical reference pair of the longest prefix of $bt_l t_{l+1} \cdots$ that occurs in $T$. Thus to compute $e_{k+m+1}$ from $e_k$ we can start at node $\overline{b}$, scan a prefix $t_i \ldots t_{j-1}$ of $t_l t_{l+1} \ldots$ until we "fall out of the tree" and canonize the reference pair $(\overline{b}, t_i \ldots t_{j-1})$ to obtain $(\overline{b}, q)$. Instead of computing $((\overline{b}, q), j)$ by some non-essential steps using equation (2) or (6) we use a function $\text{scan}$:

$$\text{scan}(T, \overline{b}, i) = \begin{cases} ((\overline{b}, \varepsilon), i), & \text{if } \overline{b} \text{ has no } t_i\text{-edge} \\ ((\overline{b}, p), i + |p|), & \text{else if } |p| < r - l + 1 \\ \text{scan}(T, \overline{b}, i + |p|), & \text{otherwise} \\ \end{cases}$$

where $\overline{b} \overset{(l,r)}{\rightarrow} \overline{p}$ is a $t_i$-edge

$p$ is the longest common prefix of $t_l \ldots t_r$ and $t_l t_{l+1} \ldots$

If we use $\text{scan}$ to compute $e_{k+m+1}$ from $e_k$ we do not need equation (2) and (6). Furthermore, from Lemma 5.3, Statement 1, we learn that equation (6) is not necessary. Hence we can transform $ukk_1$ into the following equivalent function $ukk_2$:

---

The sentinel ensures that this must happen before $t_l t_{l+1} \ldots$ is exhausted, since it cannot be a nested suffix.
\[ ukk_2(T, L, (\overline{b}, \varepsilon), i) = \begin{cases} 
T, & \text{if } i = n + 1 \\
ukk_2(T, L, (\overline{h}, q), j), & \text{else if } j > i \\
ukk_2(T \cup ((\overline{h}, q), j), L, (\overline{r}, q), j + 1), & \text{else if } (\overline{h}, q) = (\text{root}, \varepsilon) \\
ukk_2(T \cup ((\overline{h}, q), j), L, (\overline{L}, q), \varepsilon), j), & \text{otherwise} \\
\text{where } ((\overline{h}, q), j) = \text{scan}(T, \overline{h}, i) 
\end{cases} \] (8)

\[ ukk_2(T, L, (\overline{b}, cw), i) = ukk_2(T \cup ((\overline{b}, cw), i), L', (\overline{b}', u'), i) \]
\[ L' = L \cup \{ (\overline{b}cw, \overline{b}'u') \} \] (12)

Notice that equations (10) and (11) result from substituting \((\overline{b}, \varepsilon)\) by \((\overline{h}, q)\) and \(i\) by \(j\) in equation (3) and (4). This is correct, since \((\overline{h}, q) = (\overline{b}, \varepsilon)\), whenever \(i = j\). Obviously, the program transformation from \(ukk_1\) to \(ukk_2\) does not affect the linear time complexity, since a sequence of \(m\) non-essential \(ukk_3\)-derivation steps with a single character comparison is transformed into a single non-essential \(ukk_2\)-derivation step with \(m\) character comparisons, that are done in the same order. However, by the use of \(\text{scan}\), the index \(i\) starts to advance through the string without extra calls to \(ukk_1\). This is where we give up the online property. At the same time, this is where we gain the slight speed advantage of \(mec\) over \(ukk\) [16] by getting rid of successive calls to \(ukk_1\) and \(\text{canonize}\).

The next step is to eliminate the single non-essential steps in the derivation of the form
\[ e_0 = ukk_2(\emptyset, \emptyset, (\text{root}, \varepsilon), 1) \Rightarrow e_1 \cdots \Rightarrow e_N = \text{cst}(t). \]
Let \(0 < k < N\) and assume that \(e_k = ukk_2(T, L, (\overline{h}, q), j)\) is derived from the expression \((e_{k-1} = ukk_2(T, L, (\overline{b}, \varepsilon), i)\) by an application of equation (9), where \(((\overline{h}, q), j) = \text{scan}(T, \overline{h}, i)\). Since \(t\) has a sentinel, \(j \leq n\). Let \(q = \varepsilon\). Then we can derive \(e_{k+1}\) from \(e_k\), using equation (10) or (11). Since \(((\overline{h}, q), j) = \text{scan}(T, \overline{h}, j)\) we find that \(e_{k+1}\) equals the right hand side of equation (10) or (11). Let \(q \neq \varepsilon\). Then only equation (12) can be applied to \(e_k\) deriving \(e_{k+1} = ukk_2(T \cup ((\overline{h}, q), j), L', (\overline{b}', u'), j), \)
\[ \text{where } (\overline{b}', u') = \text{link}(T, L, (\overline{h}, q)) \]
\[ L' = L \cup \{ (\overline{h}q, \overline{b}'u') \} \]
Hence for \(q \neq \varepsilon\) the non-essential step from \(e_{k-1}\) to \(e_k\) can be merged with the step from \(e_k\) to \(e_{k+1}\), if we substitute equation (9), yielding the following equivalent function \(ukk_3\).

\[ ukk_3(T, L, (\overline{b}, \varepsilon), i) = \begin{cases} 
T, & \text{if } i = n + 1 \\
ukk_3(T \cup ((\overline{h}, q), j), L, (\overline{r}, q), j + 1), & \text{else if } (\overline{h}, q) = (\text{root}, \varepsilon) \\
ukk_3(T \cup ((\overline{h}, q), j), L, (\overline{L}, q), \varepsilon), j), & \text{else if } q = \varepsilon \\
ukk_3(T \cup ((\overline{h}, q), j), L', (\overline{b}', u'), j), & \text{otherwise} \\
\text{where } ((\overline{h}, q), j) = \text{scan}(T, \overline{h}, i) \\
(\overline{b}', u') = \text{link}(T, L, (\overline{h}, q)) \\
L' = L \cup \{ (\overline{h}q, \overline{b}'u') \} 
\end{cases} \] (13)

\[ ukk_3(T, L, (\overline{b}, cw), i) = ukk_3(T \cup ((\overline{b}, cw), i), L', (\overline{b}', u'), i) \]
\[ \text{where } (\overline{b}', u') = \text{link}(T, L, (\overline{b}, cw)) \]
\[ L' = L \cup \{ (\overline{b}cw, \overline{b}'u') \} \] (17)

Obviously, \(ukk_3\)-derivation steps are always essential. Furthermore, the transformation from \(ukk_2\) to \(ukk_3\) does not affect the linear time complexity. As the next step we synthesize the definition of a function \(mec\) with the following properties:
\[
mc(T, L, (\overline{b}, u), i) = \begin{cases} 
\uk_3(T, L, (\overline{b}, u), i + 1), & \text{if } (\overline{b}, u) = (\text{root}, \varepsilon) \\
\uk_3(T, L, (L(\overline{b}), u), i), & \text{if } \overline{b} \neq \text{root} \text{ and } u = \varepsilon \\
\uk_3(T, L', (\overline{b}', u'), i), & \text{if } u \neq \varepsilon 
\end{cases}
\]

where \((\overline{b}', u') = \link(T, L, (\overline{b}, u))\).

\[
L' = L \cup \{(b, b' u')\}
\]

Consider the following cases:

1. \((\overline{b}, u) = (\text{root}, \varepsilon)\). Then \(\mc(T, L, (\overline{b}, u), i) = \uk_3(T, L, (\overline{b}, u), i + 1)\). If \(i = n\) then \(\uk_3(T, L, (\overline{b}, u), i + 1)\) reduces to \(T\) by an application of equation (13). If \(i < n\) then let \(((h, q), j) = \text{scan}(T, \overline{b}, i + 1)\). Now \(\uk_3(T, L, (\overline{b}, u), i + 1)\) reduces to

\[
\begin{align*}
\uk_3(T \cup ((\overline{h}, q), j), L, (\overline{h}, q), j + 1), & \text{ if } (\overline{h}, q) = (\text{root}, \varepsilon) \\
\uk_3(T \cup ((\overline{h}, q), j), L, (L(\overline{h}), \varepsilon), j), & \text{ if } \overline{h} \neq \text{root} \text{ and } q = \varepsilon \\
\uk_3(T \cup ((\overline{h}, q), j), L', (\overline{b}', u'), j), & \text{ if } q \neq \varepsilon 
\end{align*}
\]

where \((\overline{b}', u') = \link(T, L, (\overline{h}, q))\) and \(L' = L \cup \{(h q, b' u')\}\). By definition, the three expressions are equal to \(\mc(T \cup ((\overline{h}, q), j), L, (\overline{h}, q), j)\).

2. \(\overline{b} \neq \text{root} \text{ and } u = \varepsilon\). Then \(\mc(T, L, (\overline{b}, u), i) = \uk_3(T, L, (L(\overline{b}), \varepsilon), i)\). If we let \(((h, q), j) = \text{scan}(T, L(\overline{b}), i)\), then \(\uk_3(T, L, (L(\overline{b}), \varepsilon), i)\) reduces to

\[
\begin{align*}
\uk_3(T \cup ((\overline{h}, q), j), L, (\overline{h}, q), j + 1), & \text{ if } (\overline{h}, q) = (\text{root}, \varepsilon) \\
\uk_3(T \cup ((\overline{h}, q), j), L, (L(\overline{h}), \varepsilon), j), & \text{ if } \overline{h} \neq \text{root} \text{ and } q = \varepsilon \\
\uk_3(T \cup ((\overline{h}, q), j), L', (\overline{b}', u'), j), & \text{ if } q \neq \varepsilon 
\end{align*}
\]

where \((\overline{b}', u') = \link(T, L, (\overline{h}, q))\) and \(L' = L \cup \{(h q, b' u')\}\). By definition, the three expressions are equal to \(\mc(T \cup ((\overline{h}, q), j), L, (\overline{h}, q), j)\).

3. \(u \neq \varepsilon\). Then \(\mc(T, L, (\overline{b}, u), i) = \uk_3(T, L, (\overline{b}, u'), (\overline{b}', u'), i)\) where \((\overline{b}', u') = \link(T, L, (\overline{b}, u))\) and \(L' = L \cup \{(b u, b' u')\}\). Consider the following subcases:

- \(u' = \varepsilon\). Let \(((\overline{h}, q), j) = \text{scan}(T, \overline{b}', i)\). Then \(\uk_3(T, L', (\overline{b}', u'), i)\) reduces to

\[
\begin{align*}
\uk_3(T \cup ((\overline{h}, q), j), L', (\overline{h}, q), j + 1), & \text{ if } (\overline{h}, q) = (\text{root}, \varepsilon) \\
\uk_3(T \cup ((\overline{h}, q), j), L', (L(\overline{h}), \varepsilon), j), & \text{ if } \overline{h} \neq \text{root} \text{ and } q = \varepsilon \\
\uk_3(T \cup ((\overline{h}, q), j), L'', (\overline{b}', u''), j), & \text{ if } q \neq \varepsilon 
\end{align*}
\]

where \((\overline{b}'', u'') = \link(T, L', (\overline{h}, q))\) and \(L'' = L' \cup \{(h q, b'' u'')\}\). By definition, the three expressions are equal to \(\mc(T \cup ((\overline{h}, q), j), L', (\overline{h}, q), j)\).

- \(u' \neq \varepsilon\). Let \((\overline{b}'', u'') = \link(T, L', (\overline{b}', u'))\) and \(L'' = L' \cup \{(b'' u', b'' u'')\}\). Then \(\uk_3(T, L', (\overline{b}', u'), i)\) reduces to \(\uk_3(T \cup ((\overline{h}, q), i), L'', (\overline{b}'', u''), i)\), which equals \(\mc(T \cup ((\overline{h}, q), i), L', (\overline{b}', u'), i)\).

Putting it all together we get the following definition of \(\mc\):
$$mcc(T,L,(\overline{b},u),i) = \begin{cases} T, & \text{if } i = n \text{ and } (\overline{b},u) = (\text{root},\varepsilon) \\ \text{mcc}(T \cup ((\overline{b}, q), j), L, (\overline{b}, q), j), & \text{else if } u = \varepsilon \\ \text{mcc}(T \cup ((\overline{b}, q), j), L', (\overline{b}, q), j), & \text{else if } u' = \varepsilon \\ \text{mcc}(T \cup ((\overline{b'}, u'), i), L', (\overline{b'}, u'), i), & \text{otherwise} \\ \end{cases}$$

where $(\overline{b'}, u') = \text{link}(T, L, (\overline{b}, u))$

$L' = L \cup \{ (\overline{b}, u, i + 1) \}$

\((\overline{b}, q), j) = \begin{cases} \text{scan}(T, \overline{b}, i + 1), & \text{if } (\overline{b}, u) = (\text{root},\varepsilon) \\ \text{scan}(T, L(\overline{b}), i), & \text{else if } u = \varepsilon \\ \text{scan}(T, \overline{b'}, i), & \text{else if } u' = \varepsilon \\ \end{cases}$$

This definition of \(mcc\) is equivalent to the one we have developed directly in [16]. From the specification of \(mcc\) it is easy to see that the only difference between \(ukk_{\delta}\) and \(mcc\) is that the computation of some information is delayed one step in \(mcc\). There is no difference in the order or number of computation steps.

**Proposition 5.4** For \(n = |t|\), \(mcc\{\text{root} \overline{t}\}, \emptyset, (\text{root},\varepsilon), 1\) returns \(cst(t)\) in \(O(n)\) time.

**Proof** By construction of \(mcc\), we have

\[
mcc\{\text{root} \overline{t}\}, \emptyset, (\text{root},\varepsilon), 1 = ukk_{\delta}\{\text{root} \overline{t}\}, \emptyset, (\text{root},\varepsilon), 2 = ukk\emptyset, \emptyset, (\text{root},\varepsilon), 1 = ukk\emptyset, \emptyset, (\text{root},\varepsilon), 1 = cst(t)
\]

Since \(mcc\) is derived from \(ukk\) by eliminating non-essential derivation steps, without affecting the number or order of essential steps, \(mcc\) inherits the linear time property. \(\Box\)

### 5.2 Synchronization Points between ukk and mcc

Let us call “point i” the situation after

- \(ukk\) has constructed the suffix tree \(cst(t_1 \ldots t_i)\),
- \(mcc\) has constructed the \(A^+\)-tree \(T(t_1 \ldots t_n)\), i.e. the suffix \(t_1 \ldots t_n\) has just been inserted.

At this point, \(ukk\) has read no character of \(t\) beyond \(t_i\). If \(t_i\) does not occur to the left in \(t\), it behaves as a sentinel for \(t_1 \ldots t_i\), and both \(ukk\) and \(mcc\) will have constructed \(cst(t_1 \ldots t_i)\), and no character beyond \(t_i\) has been read. But generally, \(mcc\) has scanned further in \(t\). Let us call the additional characters read by \(mcc\) its *lookahead at point i*.

**Proposition 5.5** Let \(cw = \text{tail}(t_i \ldots t_n)\) for some character \(c\) and some string \(w\). The lookahead of \(mcc\) at point \(i\) is

\[
\epsilon, \text{ if } head(t_1 \ldots t_n) = \epsilon
\]

\[
uc, \text{ if } head(t_1 \ldots t_n) = t_i u.
\]

**Proof** Intuitively, it is clear that \(t\) need not be scanned beyond \(uc\), in order to insert the new open edge \(t_i u \Rightarrow \). Formally, this can be verified against the implementation of \(mcc\) given in Section 5.1. \(\Box\)
What does this mean with respect to practical matters? Online construction is attractive when the suffix tree is intended to be used to search for first occurrences of words in $t$. If a word occurs in $t$, only the suffix tree for the prefix of $t$ ending with the first occurrence must be constructed. Further queries may further expand the tree. Thus, suffix tree construction time is amortized over a series of queries. This is the practical advantage of $ukk$ being an online algorithm.

With the complete input string available — say as a character file —, it does not really matter whether the partial tree construction stops exactly after the first occurrence of the search key, or some characters beyond it. $mcc$ may as well be interleaved with queries for first occurrences, and in this sense, it shares the advantages of a truly online construction. On the other hand, when $t$ is incrementally calculated by some other computation — say as a character stream —, then the difference matters: $ukk$ is more lazy than $mcc$, and the extra characters called for by $mcc$ may induce an overhead of arbitrary dimension.

6 An Explanation of Weiner’s Algorithm

In this section we go back to the roots and take a look at the “Algorithm of the Year 1973” (D.E. Knuth according to [20]).

Our explanation of $wrf$ is quite different from the treatment by Chen and Seiferas [10]. They restate Weiner’s algorithm in a less technical, even prosaic form. Our approach is to relate $wrf$ to $ukk$. We shall explain $wrf$ using today’s terminology, thus revealing its close relation to the algorithms discussed in the previous sections.

6.1 An Abstract Explanation

Before we enter the detailed analysis, let us first take a look at Weiner’s algorithm in terms of our abstract tree construction operations of Section 3. $wrf$ reads the input string $t$ from right to left, and successively inserts suffixes, shortest first. Figure 6 shows how the suffix tree arises from a series of add/split-operations. As with $ukk$ and $mcc$, the crux lies in the efficient way to move from one insertion point to the next, e.g., from node $\overline{a}$ to node $\overline{ad}$. Having read through all the previous sections, you might say: well — just follow the suffix link $\overline{ad} \longrightarrow \overline{d}$ in reverse direction! This idea is not totally wrong. But the general case is not as simple, and besides, reverse links are more expensive, and they usually exist only after we needed them ...

6.2 Traversing a Tree that we do not Construct

Let us assume it is 1973 and little is known about suffix trees. The first natural thing to think of is online construction, successively building the tree for longer and longer prefixes of $t$. But immediately, a problem arises: existing leaf edges will have to be extended for each new character, leading to an $O(n^2)$-algorithm. Since this problem will only be solved by Ukkonen’s open edges in 1992, let us instead process $t$ from right to left. This way,

\footnote{Weiner [26] calls the suffix tree prefix tree, and vice versa, and the overall treatment is very technical.}

18
leaves will always represent a suffix and need to be changed less frequently. This decision is quite logical — but it will bring us into tremendous difficulties shortly. Anyway: we will be building the tree successively for longer and longer suffixes of \( t \), so we have an online property in the reverse direction. Let us call this the anti-online property.

Suppose \( as \) is a suffix of \( t \). To obtain \( cst(as) \) from \( cst(s) \), a naive anti-online algorithm determines the longest prefix \( u \) of \( as \) that is an \( s \)-word. This is accomplished by walking down the path for \( as \) in \( cst(s) \) as far as possible. Let \( uv = as \). One of the following cases will arise:

1. If \( \overline{u} \) is a leaf in \( cst(s) \) then the leaf edge \( \overline{y} \rightarrow \overline{u} \) is replaced by the leaf edge \( \overline{y} \rightarrow \overline{uv} \).

2. If \( \overline{u} \) is not a leaf in \( cst(s) \) then the algorithm splits for \( \overline{u} \) if necessary, and adds an edge \( \overline{u} \rightarrow \overline{uv} \).

Later authors will suggest similar naive versions of other algorithms [19, 15], and it will be shown that their efficiency is \( \mathcal{O}(n \log n) \) in the expected case [6]. The factor \( \log n \) comes from walking the tree from the root to the point of insertion. For an \( \mathcal{O}(n) \)-algorithm we must access this point in \( \mathcal{O}(1) \). As the string \( u \) above equals \( \alpha^{-1}(as) \), our problem is solved, if for each iteration we can hop directly from one active prefix node to the next. And of course, we know exactly where it is:

**Proposition 6.1** There is an edge \( \overline{u} \rightarrow \overline{x} \) in \( cst(s) \), s.t. \( \alpha^{-1}(s) = uv \) and \( w \) is non-empty.

**Proof** Let \( u \) be the longest prefix of \( s \) that is right-branching in \( s \). Then \( u \) is a nested prefix of \( s \). Thus we can conclude \( \alpha^{-1}(s) = uv \) for some string \( v \). Moreover, there is a non-empty string \( w \), s.t. \( \alpha^{-1}(s)w = s \). Hence there is an edge \( \overline{u} \rightarrow \overline{x} \) in \( cst(s) \). \( \square \)
So the “old” active prefix is always at hand, just above the leaf inserted in the previous step. But how do we hop to the “new” one in $O(1)$?

Glancing ahead into the future, we see Ukkonen’s online algorithm swinging easily from active suffix to active suffix, using the suffix links. We are doing an anti-online construction, and are interested in active prefixes. If only we had $cst(s^{-1})$ available! Since $\alpha^{-1}(as)$ is a prefix of $a\alpha^{-1}(s)$ we then could determine $\alpha^{-1}(as)$ by following the (reverse) prefix links, shortening $\alpha^{-1}(s)$ from the right, until we find a prefix $p$, such that $ap^{-1}$ occurs in $cst(s^{-1})$. If such a $p$ exists then $\alpha^{-1}(as) = ap^{-1}$. Otherwise $\alpha^{-1}(as) = \varepsilon$.

**Example 6.2** Let $s = bedeabcbcdcbde$. Figure 7 shows the relevant parts in $cst(s^{-1})$ (plus the new outgoing $a$-edge from node $\overline{bcd}$) and the way from $\alpha(s^{-1}) = edcb$ to $\alpha((as)^{-1}) = cba$. For the sake of comparison with Figure 8, reference pairs are written from right to left. □

Of course, we cannot simply construct the reverse prefix tree, since this is the dual of the problem we started to solve. But, with some additional effort, we can use the suffix tree to simulate the above walk through the reverse prefix tree! This is the essential idea of Weiner’s algorithm, and at the same time the reason for its extra complexity.

Let us consult Proposition 2.12. From 2.12.1 and 2.12.2 we know that (and how) $(cst(s))^{-1}$ approximates the reverse prefix tree. From 2.12.3 we learn that the reversed edges of $cst(s)$ are the suffix links of $(cst(s))^{-1}$, i.e., they approximate the prefix links! Thus if we make the edges of $cst(s)$ bidirectional, this will be sufficient to approach $\alpha^{-1}(as)$ from $\alpha^{-1}(s)$.

A final problem remains, and its solution is less elegant and much more expensive. After all relevant suffixes are inserted, Ukkonen’s algorithm follows an edge in the suffix tree downward. By analogy, we shall need to walk along a prefix edge once before $\alpha^{-1}(as)$ is reached. This means we must make an additional effort to record prefix edges between the nodes of $cst(s)$. Summing up, we need the following extra information:

1. The edges of $cst(s)$ must be bidirectional, such that we can traverse them upwards.
2. For each node in $cst(s)$ and each $a \in A$ we must indicate whether this node would have an $a$-edge in $cst(s^{-1})$. We call this a pending prefix edge.
3. If the target node of this edge happens to be also a node in $cst(s)$, then we record this as a proper prefix edge.
This is how we now simulate the traversal of prefix links in $cst(s^{-1})$ by using $cst(s)$ and this auxiliary information: the traversal starts at the leaf below the active prefix, i.e. at $\overline{s}$, and moves upward until an $a$-prefix edge is indicated. If the edge is pending, we must take a detour higher up in the tree, recording its length (in characters), until we hit a node which has a proper $a$-prefix edge. We follow this edge, and then proceed downward in $cst(s)$ according to the recorded length of the detour.

Example 6.3 Let $s = bcdeabcdfbede$ as in Example 6.2. Figure 8 shows the relevant parts in $cst(s)$ and the way from $\alpha^{-1}(s) = bcde$ to $\alpha^{-1}(as) = abc$. Node $bc$ is the one with the pending prefix edge, where the detour $(up, over, down)$ starts. The extra parenthesis around $bc$ indicate the characters which account for the length of the detour. It is not typical that this traversal passes the root, but an even more sophisticated example would be necessary to demonstrate this. □

During this traversal, we must also create and update the extra information, and make sure that we can do all this in $O(1)$ on the average (see Section 6.3).

Summing up, we may say that Weiner’s algorithm has a touch of tragic and heroism: faced with the problem of growing leaf-edges, it turns to anti-online construction. This means having to traverse the reverse prefix tree while only the suffix tree is to be constructed. This adds an almost unsurmountable amount of difficulty — but $wrf$ succeeds in handling it within the linear time constraint.

6.3 Extra Costs of wrf

Here we detail the extra costs in time and space that result from $wrf$’s simulated traversal of the reverse prefix tree. Recall the extra information required by $wrf$ (see item (1), (2), (3) on page 20).

The extra pointer needed for (1) is equivalent to the effort of storing suffix links in $ukk$ and $mcc$. It is the extra data structures for pending and proper prefix edges which make $wrf$ more space consuming, and their maintenance makes it slower than the others.
But still, this extra information can be maintained with a fixed effort per node visited. When \( \overline{uv} \) is split for \( \overline{w} \), this node inherits its proper and pending prefix edges from the leaf \( \overline{uw} \). The new leaf, representing the longest suffix, naturally has no prefix edges when created. Finally, prefix edges of a node on the path from \( \alpha^{-1}(s) \) upward must be updated. They all have a pending \( a \)-prefix edge now, and if there is an explicit node \( \overline{ur} \), we record the proper prefix edge \( \overline{uv} \rightarrow \overline{uw} \).

At this point, we are left with one final question: while a traversal along prefix links can be easily shown to add up to \( \mathcal{O}(n) \) node visits overall, it is not obvious that the same is true when we traverse the suffix tree instead. Our "detour" may take us up all the way to the root, and back down. This is also exemplified in Figure 8. In fact, if this happened at each iteration, we would essentially be back at the naive anti-online algorithm. How can we prove that this form of traversal does not visit more than \( \mathcal{O}(n) \) nodes in total?

Lemma 6.4 As above, let \( \overline{r} \) be the node encountered which has a proper \( a \)-prefix edge, and let \( \overline{uw} = \alpha^{-1}(s) \). Then, there is no node between \( \overline{ur} \) and \( \overline{uw} \).

Proof The only possibility for a node between \( \overline{ur} \) and \( \overline{uw} \) is when \( v = xy, x \neq \varepsilon, y \neq \varepsilon \), and \( \overline{uv} \) is an explicit node. It is an inner node, and the remark after Proposition 2.9 applies. So its suffix link points to the node \( \overline{ur} \), which then has a proper \( a \)-prefix edge. This contradicts the definition of \( \overline{r} \) of being the first such node on the traversal. □

So from the "summit" \( \overline{r} \) of the detour we descent at most one node. We now consider the depth of the nodes (from the root) visited: it is first decreased by the detour, and then increased by at most 1. The tree has \( \mathcal{O}(n) \) nodes. Since the sum of all increases is bounded by \( n \), the decreases cannot add up to more than \( 2n \). Hence the number of nodes visited over all detours is \( \mathcal{O}(n) \).

7 Conclusion

We have reached the end of our investigation, and the conclusion is clear: the three suffix tree constructions considered — \( wrf \), \( mec \), and \( ukk \) — are more closely related than is commonly assumed. While all three are \( \mathcal{O}(n) \)-algorithms, their relative virtues are different:

- \( ukk \) is online, the most elegant construction, and the clue to understanding the others,
- \( mec \) is the most efficient construction, by a small margin over \( ukk \),
- \( wrf \) has no practical virtue (it uses significantly more time and space), but remains to be a true historic monument in the area of string processing.

The notion of active suffixes, suffix links, and the duality between suffix link trees and prefix trees are the cardinal points of linear time suffix tree construction. Although there is no truly formal way to express this, we conjecture that any sequential suffix tree construction not based on these concepts will fail to meet the \( \mathcal{O}(n) \)-criterion. This does not pertain to parallel constructions like [14].
8 Acknowledgments

Gene Lawler encouraged us to exploit our duality observation for explaining suffix tree construction. Dan Gusfield and Richard Karp directed our attention to the manuscript by Pratt [20]. Dan Gusfield also provided a carefully written exposition of Weiner’s algorithm. Many discussions with Esko Ukkonen improved our understanding of suffix trees. The careful comments of the referees gave valuable hints to improve the exposition. All their contributions are truly appreciated.
